Bumps, breathers, and waves in a neural network with spike frequency adaptation

S. Coombes and M.R. Owen

(Dated: March 2, 2005)

In this Letter we introduce a continuum model of neural tissue that include the effects of so-called spike frequency adaptation (SFA). The basic model is an integral equation for synaptic activity that depends upon the non-local network connectivity, synaptic response, and firing rate of a single neuron. A phenomenological model of SFA is examined whereby the firing rate is taken to be a simple state-dependent threshold function. As in the case without SFA classical Mexican-Hat connectivity is shown to allow for the existence of spatially localized states (bumps). Importantly an analysis of bump stability using recent Evans function techniques shows that bumps may undergo instabilities leading to the emergence of both breathers and traveling waves. Moreover, a similar analysis for traveling pulses leads to the conditions necessary to observe a stable traveling breather. Direct numerical simulations both confirm our theoretical predictions and illustrate the rich dynamic behavior of this model, including the appearance of self-replicating bumps.

Neural field models of Wilson-Cowan [1] or Amari [2] type have been intensively studied since the 1970’s with regard to the dynamics of large scale brain activity. This has had a major impact in helping not only to understand the dynamics seen in brain slice preparations [3], but also in understanding EEG rhythms [4], visual hallucinations [5, 6], short term memory [7], motion perception [8], representations in the head-direction system [9] and feature selectivity in the visual cortex [10]. For a recent review of these phenomena see [10]. Typically, however, such models do not incorporate any of the slow intrinsic processes known to modulate single neuron response. In this Letter we focus on the effects of such a process, namely spike frequency adaptation (SFA). SFA is a commonly observed property of many single neurons and has been linked to the presence of a Ca^{2+} gated K^{+} current, I_{AHP} [12]. The generation of an action potential leads to a small calcium influx that increments I_{AHP}, with the end result being a decrease in the firing rate response to persistent stimuli. Both biophysical and phenomenological models of this process have been studied in the context of neural computation at the single cell level (see for example the work of Liu and Wang [13]). In this Letter we show that SFA can also lead to novel dynamic instabilities at the network level. To illustrate this we focus on a one-dimensional neural field model with short-range excitation and long range inhibition, and consider a simple model of SFA.

In more detail we analyze a neural field model with synaptic activity \( u = u(x, t), x \in \mathbb{R}, t \in \mathbb{R}^+, \) governed by the integral equation

\[
  u = \eta * w \otimes H(u - h).
\]

Here, the symbol \(*\) represents a temporal convolution in the sense that

\[
  (\eta * f)(x, t) = \int_0^t \eta(s) f(x, t - s)ds,
\]

and \( \otimes \) represents a spatial convolution such that

\[
  (w \otimes f)(x, t) = \int_{-\infty}^{\infty} w(y)f(x - y, t)dy.
\]

The function \( \eta(t) \) (with \( \eta(t) = 0 \) for \( t < 0 \)) represents a synaptic filter, whilst \( w(x) \) is a synaptic footprint describing the anatomy of network connections. The function \( H \) represents the firing rate of a single neuron, and we shall take it to be a Heaviside function such that \( H(x) = 1 \) for \( x \geq 0 \) and is zero otherwise. Hence, we identify \( h \) as a firing threshold. In the absence of an SFA current we would recover the standard model (without SFA), by setting \( h \) to be a constant, say \( h_0 \). To mimic the effects of SFA we consider an adaptive threshold that changes most when synaptic input to a neuron is large. One such simple adaptive scheme, in the spirit of that discussed in [13], can be written

\[
  h_t = -(h - h_0) + \kappa H(u - \theta),
\]

for some SFA threshold \( \theta \) and positive \( \kappa \). In fact a linear threshold dynamics has previously been considered in [10], and can be traced all the way back to work by Hill in 1936 [14]. However, the form of nonlinear threshold dynamics chosen here leads to interesting new phenomena. For the rest of this paper we work with the choice \( \eta(t) = ae^{-\omega t}H(t) \) and \( w(x) = (1 - |x|)e^{-|x|} \). The extension to other synaptic filters and footprints is straightforward [15].

First we construct time-independent solutions \( (u, h) = (q(x), p(x)) \) that satisfy

\[
  q = w \otimes H(q - p),
  p = \begin{cases} h_0 & q < \theta, \\ h_0 + \kappa & q \geq \theta \end{cases}
\]

A localized bump solution is one that satisfies \( q(x) > h_0 + \kappa \) for \( x \in [0, x_1], \) \( \theta < q(x) < h_0 + \kappa \) for \( x \in (x_1, x_2), \)
h_0 < q(x) \leq \theta \text{ for } x \in [x_2, x_3) \text{ and } q(x) < h_0 \text{ otherwise.}

Furthermore, we restrict attention to symmetric solutions for which q(x) = q(-x) with x_3 > x_2 > x_1 > 0.

An explicit solution may be constructed as

\[ q(x) = \left( \int_{-x_1}^{x_1} + \int_{x_1}^{x_2} + \int_{x_2}^{x_3} \right) w(x-y)dy. \tag{6} \]

The unknowns x_1, x_2, and x_3 are found by the simultaneous solution of

\[ q(x_1) = h_0 + \kappa, \quad q(x_2) = \theta, \quad q(x_3) = h_0. \tag{7} \]

We identify E(\lambda) as the Evans function for the bump, such that solutions are stable if Re \lambda < 0. A recent discussion of the use of Evans function techniques in neural field theories can be found in [16]. Using the fact that \[ L[\eta_0(0)] = 1 = L[\eta_1(0)] \] we directly calculate that \[ E(0) = 0 \] with corresponding eigenfunction \[ q_0(x) \], as expected for a system with translation invariance. By determining the zeros of the Evans function we are now in a position to probe the manner in which a bump may go unstable. One natural way to find the zeros of E(\lambda) is to write \[ \lambda = \nu + i\omega \] and plot the zero contours of Re E(\lambda) and Im E(\lambda) in the (\nu, \omega) plane. The Evans function is zero where the lines intersect. There are basically two different routes to instability: i) for sufficiently small \kappa an eigenvalue crosses to the right half complex plane on the real axis, and one sees a bump go unstable in favor of a traveling pulse with increasing \lambda, and ii) for larger \kappa a pair of complex-conjugate eigenvalues cross through the imaginary axis to the right half complex plane and a bump goes unstable in favor of a breathing solution, with increasing \alpha. These two scenarios are illustrated in Fig. 2 and Fig. 3 respectively.

It is possible to extend this analysis to traveling wave solutions, and in particular the type of solution shown in Fig. 2. Following the approach in [16] we introduce the coordinate \[ \xi = x - ct \] and seek functions \[ \tilde{u}(\xi, t) = u(x - ct, t) \] and \[ \tilde{h}(\xi, t) = h(x - ct, t) \] that satisfy (1) and (4). In the (\xi, t) coordinates we have that

\[ \tilde{u}(\xi, t) = \int_{-\infty}^{\infty} dw y \int_{0}^{\infty} ds \eta(s) y \tilde{H}(\tilde{u}(\xi - y + cs, t - s) - \tilde{h}(\xi - y + cs, t - s)), \]

\[ \tilde{h}(\xi, t) = h_0 + \kappa \int_{0}^{\infty} ds \eta(s) H(\tilde{u}(\xi + cs, t - s) - \theta). \]

\[ \text{FIG. 1: (Color online). Analytical bump solution } (q, p) \text{ (as solid and dashed lines respectively) with } h_0 = 0.04 \theta = 0.1, \kappa = 0.16. \text{ Here } x_1 = 1.48, x_2 = 1.60 \text{ and } x_3 = 1.67. \text{ The inset shows a blowup of the solution around the window containing the points } x_1, x_2 \text{ and } x_3. \text{ At these parameter values this type of solution exits for } \kappa < 0.32. \]
Hence the solution for $q$ in the simple form

$$
\xi_1 = 0 \text{ the simultaneous solution of the four threshold crossing conditions}
$$

$$
q(\xi_1) = \theta \quad q(\xi_2) = p(\xi_2) \quad q(\xi_3) = \theta \quad q(\xi_4) = p(\xi_4),
$$

may be used to determine the remaining four unknowns. Linearising (15) and (16) about the travelling pulse and seeking solutions of the form $(u(\xi), h(\xi))e^{\lambda t}$ gives

$$
u(\xi) = A_2(\xi, \lambda)[u(\xi_2) - h(\xi_2)] + A_4(\xi, \lambda)[u(\xi_4) - h(\xi_4)],
$$

$$
b(\xi) = A_1(\xi, \lambda)u(\xi_1) + A_3(\xi, \lambda)u(\xi_3),
$$

where $A_i(\xi, \lambda) = -\mathcal{H}(\xi_i - \lambda)/q'(\xi_i)$ for $i = 1, 3$ and $A_4(\xi, \lambda) = \mathcal{U}(\xi - \xi, \lambda)/F'(\xi)$. Here, $F(s) = q(s) - p(s)$ and

$$
\mathcal{U}(\xi, \lambda) = \int_0^\infty dyw(y - \xi)\eta(y)e^{-\lambda y},
$$

$$
\mathcal{H}(\xi, \lambda) = \kappa\eta\xi(\xi/c)e^{-\lambda y/c}.
$$

The derivatives $q'$ and $p'$ are easily calculated as $\eta(\xi - \psi)/c$ and $(p - h_0 - \kappa\mathcal{H}(q - \theta))/c$ respectively. Following along identical lines to the construction of the Evans function for a bump we obtain $\mathcal{E}(\lambda) = |I_3 - \mathcal{A}(\lambda)| = 0$, where the $3 \times 3$ matrix $\mathcal{A}(\lambda)$ has components $[\mathcal{A}(\lambda)]_{ij} = A_{ij}(\xi, \lambda)$. A straightforward calculation establishes that $(u, h) = (q', p')$ is an eigenfunction with $\lambda = 0$ as expected. Interestingly, our analysis shows that stable travelling pulses co-exist with stable bump solutions for a wide range of parameters.
range of parameter values. Moreover, it is possible that a pulse can undergo a dynamic instability with increasing $\alpha$ and then restabilize via the reverse mechanism. Direct numerical simulations in such parameter windows show the emergence of stable traveling breathers. We illustrate this phenomenon in Fig. 4. In fact direct numerical simu-

s (for Heaviside, sigmoidal and threshold linear firing rate functions) show a whole host of exotic solutions including asymmetric breathers, multiple bumps, multiple pulses, periodic traveling waves, and bump-splitting instabilities that appear to lead to spatio-temporal chaos. An example of such a splitting is shown in Fig. 5. It is interesting to note that similar bifurcations have been seen in other dissipative systems that support localized structures, in particular those of coupled cubic complex Ginzburg-Landau equations [17]. Moreover, the traveling pulses in our model exhibit particle like properties, and are reminiscent of the dispersive solitons observed in some three component reaction-diffusion systems [18]. Although such behavior may well be generic in inhomogeneous neural field models with external forcing, as in the work of Bressloff et al. [19], to our knowledge this is the first time that exotic solutions, such as stable traveling breathers, have been found in a homogeneous neural field model. We attribute this interesting new physics directly to the choice of nonlinear threshold accommodation model, since linear models, of the type studied by Hansel and Sompolinsky [10], have only shown bump instabilities leading to traveling pulses. Full details of the calculations in this paper, and further explorations of parameter space, including results in two-dimensions, will be published elsewhere.
