Focus on the success of others leads to selfish behavior

Pieter van den Berg, Lucas Molleman, & Franz J. Weissing

Introduction

Acquiring information about others is a prominent feature of the human behavioral repertoire (1-3). Observing the behavior of others can allow individuals to improve their own knowledge and skills, but it can also be instrumental in anticipating how others will behave in future social interactions. Cues that help to predict how others will behave can allow for better coordination, or for being able to outsmart others for personal gain (4, 5). Indeed, the ability to keep a mental tab about the past actions of others has been put forward as one of the main mechanisms that allowed for the evolution of cooperation in humans (6, 7).

This focus on social information comes with a spectacular capacity to imitate. Imitation and other forms of social learning govern the spread of information between individuals and are therefore at the basis of cultural change. Indeed, it has been argued that these mechanisms of transmission underlie a process of cultural evolution, which is in many ways analogous to genetic evolution (8-10). Social learning has allowed humans to rapidly adapt to all kinds of environmental circumstances, and is ultimately responsible for the wide variety of languages, habits, forms of organization, and social norms that are found across cultures (11-14). Because of this, social learning and its group-level consequences have been the object of considerable scientific scrutiny. Laboratory studies and theoretical models have gone hand in hand in respectively identifying the social learning strategies that people use (15-18), and determining how these different strategies are shaped by selection (19-21) and affect the outcome of cultural evolution (22-26). The framework of cultural evolution has been successfully applied for a range of purposes, such as understanding the spread and the loss of technologies in human societies (27, 28) and inferring the ancestry of cultural traits such as language and political organization (29-31).

Although there has been extensive focus on identifying the rules that humans use to learn from each other, the possibility that people may differ in the way they learn from others has long been ignored. Only recently, several studies (32-35) have suggested that there is substantial individual variation in the extent to which people use social information, and in the type of information they are interested in. Some individuals focus on information about the success of others (paying attention to both their decisions and the associated payoffs), whereas others are only interested in the frequencies with which behaviors occur in their social group (disregarding information about the payoffs others obtained). Moreover, individuals tend to use the same social learning strategy across different (social and non-social) contexts (34). However, it is not clear how the focus on different types of social information might affect the outcome of social interactions.

In this study, we examine the consequences of individual variation in human social learning strategies on the outcome of cooperative interactions. For this, we conducted a decision-making experiment that consisted of two parts that took place one month apart. In Part 1, subjects were divided in groups and confronted with a number of different interaction settings. In each interaction round, they were allowed to view a limited amount of information about their peers’ previous behavior and earnings. In Part 2, we assorted the same subjects in groups based on the social learning strategies they had employed in Part 1, creating groups of success-based learners and frequency-based learners. These groups were confronted with a cooperation setting, in which each subject had to decide between a selfish option and an option that benefitted the group. We analyze the outcome of the interactions in these groups and investigate whether, and to what extent, the previous behavior and earnings. In
differences in cooperation can be traced back to differences in social learning style.

**Results**

In Part 1 of the experiment, 200 subjects were divided in groups of five and confronted with four different interaction contexts in randomized order (non-social, cooperation, coordination and evasion). In each context, they made decisions between two options for 20 consecutive interaction rounds. Their decision resulted in a payoff that depended on the type of the social interaction, the decisions of their fellow group members, and also included an element of random noise. Before making a decision, subjects were given the opportunity to view a maximum of four ‘pieces of information’ about their fellow group members at a small cost, where one piece of information consisted of either a previous payoff or a previous decision of a fellow group member.

The four interaction contexts we offered are consistent with those considered in our earlier study (34), but here we focus on the three social contexts.

The results of Part 1 fully confirm the earlier observation that there are marked individual differences in both the amount of social information that individuals request, and the type of information they are interested in (34). A large majority of information requests (86.7%) were of two types: individuals either requested the decisions of all four group members in the previous round (henceforth referred to as frequency-information), or they requested both the decision and the payoff of two fellow group members (success-information). Figure 1a classifies all individual differences in social learning style.

Fig. 1. Consistent individual differences in social learning strategies. In Part 1 of the experiment, 86.7% of all information requests fell into two categories: subjects either asked for frequency-information (i.e. the decisions of all four group members in the previous round) or they asked for success-information (i.e. the combination of decision and corresponding payoff for two group members in the previous round). (a) Classification of individuals with respect to the fraction of requests an individual targeted at success-information in Part 1 of the experiment. In each social context, the histogram reveals a U-shaped distribution: most individuals had extreme social learning strategies, either requesting mainly success-information or requesting mainly frequency-information. (b) Consistency of social learning strategies across the three social contexts in Part 1 of the experiment. For each context, individuals were classified as either focused on frequency (more than 50% of their requests used for frequency-information) or focused on success (more than 50% used for success-information). The graph depicts the 8 possible combinations of frequency- and success-focus across the three social contexts; the size of the circles indicating the number of individuals falling in each category. The individuals that were consistent over all social contexts are highlighted; consistent frequency-based learners (69) in orange and consistent success-based learners (23) in purple. 92 of the 145 subjects (63.4%) that requested information in at least one round of each social context were consistent across all three contexts. (c) Consistency in the number of information requests over time (between Part 1 and Part 2 of the experiment, summed over all social contexts) and (d) consistency in type of information requested between Part 1 and Part 2 (the fraction of information pieces requested that were used for success-information, over all social contexts). In both c and d, the size of the dots indicates number of individuals (the smallest dots representing single individuals), and the red lines represent linear regressions (in both cases, $R^2 = 0.454$, $P < 0.001$).
Fig. 2. Groups of frequency-based learners achieved higher levels of cooperation than groups of success-based learners. Bars show average cooperation rates (±1 SEM) over all rounds of the social dilemma context in Part 2. Data are based on 16 groups of frequency-based learners, 8 mixed groups and 8 groups of success-based learners. The *P*-value shown in the graph refers to a Tukey–Kramer test.

As shown in Figure 2, the group composition with regard to learning strategy had a systematic and significant effect on the level of cooperation achieved in the group (One-way ANOVA, *F* = 4.772, *P* = 0.016). In particular, the cooperation level was significantly higher in groups of frequency-based learners than in groups of success-based learners (Tukey–Kramer test, *P* = 0.013), while the cooperation level in mixed groups (mostly composed of individuals with inconsistent learning strategies) was intermediate. Due to the higher cooperation levels, average payoffs were significantly higher in groups of frequency-based learners than in groups of success-based learners (One-way ANOVA, *F* = 5.083, *P* = 0.013; Tukey–Kramer test: *P* = 0.014). These results strongly suggest that differences in social learning strategies affect the outcome of social interactions.

How do the observed differences in cooperation level arise? One possibility is that frequency-based learners simply have a stronger tendency to cooperate. Our data do not support this: in the first round of the interaction, when decisions were not yet influenced by social information, cooperation levels did not differ between frequency-based learners and success-based learners (respectively 0.362±0.054 and 0.350±0.076; Fisher’s exact test, *P* = 0.839). Another possibility is that the different cooperation levels are the direct result of the different social learning strategies. To investigate this in more detail, we zoom in on how different types of social information affect subsequent behavior.

Figure 3a shows how subjects behaved after viewing success-information (both the decisions and the payoffs of two fellow group members in the previous round). Subjects were most likely to switch behavior (from cooperation to defection or vice versa) if they observed that others achieved substantially higher payoffs with the opposite behavior. Interestingly, this effect was equally strong for subjects that defected in the previous round and subjects that cooperated. In addition, subjects were generally conservative; if the observed payoff difference in favor of the other behavior was small, they tended not to change their behavior. Apart from this tendency to conservatism, the observed patterns are consistent with success-based learning as it is often implemented in models of cultural evolution (22, 26).

Figure 3b illustrates how subjects behaved after viewing frequency-information (the decisions of their four fellow group members in the previous round). In this case, the response to information was strongly affected by an individual’s own previous behavior. After having defected in the previous round, subjects were relatively likely to switch to cooperation (35% of the cases). Interestingly, this switching rate did not depend on the social information they just viewed; it was the same irrespective of the number of fellow group members that cooperated in the previous round. In contrast, subjects who had cooperated in the previous round were responsive to the information they received. The more cooperators they observed among their fellow group members, the more likely they were to continue cooperating themselves. Although this latter pattern has an element of conformism, it is quite distinct from conformism as it is generally represented in models of cultural evolution (10, 25, 26). In such models, conformism is typically modelled by a symmetric S-shaped function indicating that copying a behavior becomes disproportionally more likely the more the common behavior is in the population, causing the common behavior to become even more common over time.

Could the differences in cooperation level between groups of frequency-based learners and groups of success-based learners (as shown in Figure 2) be fully explained by the response patterns to both types of information (Figure 3)? To investigate this, we...
implemented simplified cartoon versions of the observed learning strategies in a simulation model. In the simulations, we used the same payoff functions (and payoff noise level) as in the experiment, and assumed that individuals are equally likely to request information as observed in the experiment. The probability of cooperating after not requesting information was also parameterized from our experimental observations. As illustrated in Figure 4, the differences in social learning rules can indeed account for the observed differences in cooperation.

Discussion

The results of our study can be summarized in three main points. First, our study confirms with an independent experiment that individuals differ systematically and consistently in their social learning strategies. Second, we show for the first time that the differences in learning strategies are stable over a longer time period, much like aspects of personality. Third, we demonstrate that individual differences in social learning strategies can strongly affect the outcome of social interactions. In particular, groups of success-based learners reach lower levels of cooperation than groups of frequency-based learners.

Our experiment was designed to investigate the effect of social learning strategies on the outcome of social interactions. Accordingly, we consider the finding that the cooperation level achieved in groups of success-based learners is considerably lower than cooperation in frequency-based learners the main result of this study. There were no differences in cooperation between frequency-based learners and success-based learners levels in the first interaction round. This suggests that the diverging cooperation levels do not result from differences in general cooperation tendencies, but are a direct result of how the learning strategies affect behavior. This is also supported by our simulation model. Intuitively, the effect of an individual’s social learning strategy on their cooperative behavior can be understood as follows. In a social dilemma, defection yields individually higher payoffs than co-

![Fig. 3. Cooperation rates after viewing frequency-information and success-information.](Image)

![Fig. 4. Simulation of the effect of social learning strategy on cooperation in a social dilemma. Change in cooperation rates over time for groups of five, containing only frequency-based learners (orange lines) or only success-based learners (purple lines). Lines represent averages over 100,000 replicate simulations. For both scenarios, all possible starting conditions with regard to the initial number of cooperators are shown. The social learning strategies used in the simulations are simplified cartoon versions of the learning rules observed in the experiment (as shown in figure 3).](Image)
operation, so success-based learning is likely to lead to low levels of cooperation. Frequency-based learners are not as focused on information about payoffs and are therefore less inclined to adopt the individually better-paying option (in this case, defection). Additionally, high levels of cooperation can be sustained by a positive feedback in groups of frequency-based learners: the more fellow group members are observed to cooperate, the higher the inclination of individuals to continue cooperation themselves.

Although this was not the main focus of our study, we provide strong support for our earlier finding (34) that humans differ consistently in their social learning strategies. On purpose, we modified the set-up of our experiment in several ways from that of our earlier study: groups were smaller, payoffs and information cost were different, the degree of random noise on payoffs was higher, and subjects were allowed to request fewer pieces of information. Despite these differences, the vast majority of subjects in both studies consistently used one of two learning strategies, irrespective of the social context. This strongly suggests that individual differences in social learning strategies are a robust phenomenon. This conclusion is further strengthened by the finding that the subjects of the present study tended to use causes can help provide proximate explanations of how in Part 1. In other words, differences in social learning strategy seem to be stable over time, at least over a period of one month. Model studies suggest that such time-stability can have important implications, e.g. for signaling intentions and for coordinating behavior within groups (36-39). Yet, such time-stability is rarely investigated in experimental studies. Our study is a first step, but experiments spanning a longer time period and specifically designed to study time-stability are required to really judge the stability of differences in social learning strategies.

The finding that individuals differ systematically, stably, and consistently in their learning strategies has important implications for the interpretation of empirical data, irrespective of whether these data are collected in the lab or in a field setting. For example, an interesting recent study on social learning strategies in a social dilemma in 14 Indian villages neither found support for conformism, nor for success-based learning (40). However, this conclusion is based on a statistical analysis that implicitly assumes that the underlying population is homogeneous with respect to social learning strategies. Even if conformism or success-based learning are not observed at the aggregate level, it is very well possible that the population is heterogeneous, harboring two or more coexisting social learning strategies.

The idea that humans differ fundamentally in the way they gather information was already suggested by Jung (41), but has received relatively little attention in modern systems of personality categorization such as the Five Factor Model (41, 42). This may be an important shortcoming: if individuals differ systematically in the way they collect, interpret and respond to information, they will also differ systematically in their behavior. This insight can have important implications for the interpretation of individual differences. Observed behavioral variation need not reflect differences in mental, physiological, or motivational states, but may instead result from differences in social learning strategies. Experimental studies designed to distinguish between these potential learning strategies in Part 2 of the experiment as in Part 1. In other words, differences in social learning strategy seem to be stable over time, at least over a period of one month. Model studies suggest that such time-stability can have important implications, e.g. for signaling intentions and for coordinating behavior within groups (36-39). Yet, such time-stability is rarely investigated in experimental studies. Our study is a first step, but experiments spanning a longer time period and specifically designed to study time-stability are required to really judge the stability of differences in social learning strategies.

The link between frequency-based learning and cooperation has received quite some attention in the literature around the topic of ‘cultural group selection’. This literature discusses the spread of cooperation through competition between groups, when individuals use conformist learning: the disproportional tendency to copy the majority behavior. Since this type of frequency-based learning reduces variation within groups relative to variation between groups, it makes selection between groups more effective. Some have argued that this increases the scope for the cultural evolution of group-beneficial traits (such as cooperation) (10, 50-54). However, conformism itself is neutral with regard to the content of behavior – it makes it extremely difficult for any behavior, including cooperation, to spread when initially rare (25, 55). Our experiment did not consider competition between groups, but rather measured the consequences of different learning strategies for the spread of cooperation within groups. Although frequency-based learning was employed by a large proportion of the subjects, it was quite distinct from conformism as it is usually modeled. In fact, frequency-based learning as observed in our experiment did not reduce variation within groups; it led to intermediate levels of cooperation. Also, our results strongly suggest that frequency-based learning in a social dilemma is not neutral with respect to behavior; subjects that defected in the previous round responded to information quite differently from those who cooperated. It would be interesting to develop a model of cultural group selection including both individual differences in social learning strategies and more refined versions of frequency-based learning (as observed in our experiment). It is conceivable that such a model could not only explain the evolutionary stability of cooperation (due to cultural group selection), but also the spread of cooperation when initially rare.

Materials and methods
A total of 200 subjects (mostly students, mean age: 22.9, 68.5% female) participated in the study in a laboratory at the University of Groningen. Part 1 and Part 2 consisted of respectively ten and eight sessions of 20 subjects each. In both parts, subjects were confronted with four interaction contexts (in random order) of 20 rounds each, in groups of five. At the start of each session, subjects received written general instructions that were also read aloud by the experimenters. Before each interaction context, groups were reshuffled randomly, and subjects received specific instructions on their computer screens (see SI for screen shots and the general instructions of both parts). After this, subjects completed a short questionnaire to ensure they had understood the payoff-structure of the following context. In Part 1, decision-making was framed in a context of a choice between planting different crops on a farm. In Part 2, the context of decision-making was...
framed as investment choices in a stock market. The basic payoff structures of the two parts are the same, but the payoffs, noises on payoffs, and information cost in Part 2 were scaled with a factor of 1.5 compared to Part 1 (here, values for Part 1 are given). Subjects were not aware of the identity of their group members, and were unable to see the computer screens of other participants. The experiment was run with the experimental software z-Tree (56) (code available upon request). In each context, subjects decided between two options that remained the same over the rounds of that context (we used actual crop names (Part 1) and fictitious company names (Part 2), but here we will refer to the options as A and B). All subjects made their choice simultaneously, and were then shown the resulting payoff. Before each decision, subjects could choose to collect information about the members of their group, at a cost of 2 points. At the end of Part 2, subjects were paid in private proportional to the payoffs they had accumulated over both parts (100 points = 1 euro; mean earnings of subjects that participated in both parts: €69.53; max earnings €90.30). We ensured that participants could not end with a negative point total, by giving them a large enough endowment at the start of the experiment. Sessions lasted for approximately 90 minutes.

In the social dilemma (see S1 for other contexts), payoffs of choosing respectively A and B in Part 1 were given by 

\[ \pi_A = 40 - \frac{2}{10}(1 - p) \] 
and 

\[ \pi_B = 60 + 2p, \] 
where \( p \) denotes the fraction of the subjects in the group that chose option \( A \), and \( e \) is a stochastic component, drawn from a normal distribution with mean 0 and standard deviation \( \sigma_e = 20 \). The one-shot version of this game has a single Nash equilibrium at \( (p, e) = 0 \), even though all subjects obtain a higher payoff at \( p = 1 \). This shows that collective interests and individual interests are not in conflict.

Simulations were programmed in C+ (code available upon request). We tracked the cultural evolution of cooperation through 20 rounds for groups consisting either of only frequency-based learners or only payoff-based learners. In each round, individuals received payoffs for cooperation and defection as in the experiment (including noise on payoffs). Individuals used social information with a 30% probability (as in the experiment). If they did not request information, they had a 63% or 6% probability to cooperate, depending on whether they cooperated or defected in the previous round (as in the experiment). If they did request information, the probability of cooperation was determined by the logistic regressions shown in Figure 3. Success-based learners viewed two randomly chosen peers — if both these individuals had the same behavior as the focal individual in the previous round, the focal individual was assumed to stay with their previous behavior (with a probability of 1% to switch).
