Electrolysis of solid metal oxides has been demonstrated in MgCl₂–NaCl–KCl melt at 700 °C taking the electrolysis of Ta₂O₅ as an example. Both the cathodic and anodic processes have been investigated using cyclic voltammetry, and potentiostatic and constant voltage electrolysis, with the cathodic products analysed by XRD and SEM and the anodic products by GC. Fast electrolysis of Ta₂O₅ against a graphite anode has been realized at a cell voltage of 2 V, or a total overpotential of about 400 mV. The energy consumption was about 1 kW h kg⁻¹Ta with a nearly 100% Ta recovery. The cathodic product was nanometer Ta powder with sizes of about 50 nm. The main anodic product was Cl₂ gas, together with about 1 mol% O₂ gas and trace amounts of CO. The graphite anode was found to be an excellent inert anode. These results promise an environmentally-friendly and energy efficient method for metal extraction by electrolysis of metal oxides in MgCl₂ based molten salts.

Introduction

Metal materials are crucial to our society. Metals are mainly produced by pyrometallurgical methods such as carbothermic or metallothermic reductions. However, these processes usually involve multiple steps, and are energy intensive and environmentally unfriendly.¹ ² At the end of the twentieth century, Chen et al.³ proposed the solid electrochemical reduction of TiO₂ to produce Ti in CaCl₂ molten salt, known as the FFC Cambridge process. Since then, this process has received much attention. Up till now, many metals, semi-metals and their alloys have been successfully prepared by this simple solid oxide reduction process.⁴ ⁵ The FFC Cambridge process can be summarized by following reactions.

\[
\text{MO}_x \rightarrow \text{M} + \frac{x}{2}\text{O}_2 \text{ (inert anode)}
\]

\[ n\text{MO}_x + x\text{C} \rightarrow n\text{M} + x\text{CO}_n \text{ (carbon anode, } n = 1 \text{ or } 2) \]  

(1b)

Cathodic reaction:

\[ \text{MO}_x + 2xe^{-} \rightarrow \text{M} + x\text{O}^{2-} \]  

(2)

Anodic reaction:

\[ 2\text{O}^{2-} \rightarrow \text{O}_2 + 2e (\text{inert anode}) \]  

(3a)

\[ n\text{O}^{2-} + \text{C} \rightarrow \text{CO}_n + 2ne (\text{carbon anode}) \]  

(3b)

In the above equations M represents the studied metal (e.g. Ti, Nb and Ta) or semi-metal (e.g. Si).

During electrolysis, the graphite anode is often used for its good electronic and mechanical properties. However, as shown by Reaction (3b), the anodic discharge of dissolved \(O^{2-}\) ions in CaCl\(_2\), which come from the cathode by Reaction (2), will lead to anode consumption and consequently carbon emission. Moreover, the CO\(_2\) produced at the anode can react with \(O^{2-}\) ions in the molten salt to form \(CO_3^{2-}\) ions, which will move back to the cathode and discharge to carbon and \(O^{2-}\) ions,\(^6,7\) leading to carbon contamination to the metal product, floating carbon on the surface of CaCl\(_2\) melt, as well as low current efficiency. Although many inert anodes have been developed for \(O_2\) evolution,\(^8\)–\(^12\) they are yet pending for commercial verification. At present, similar to the electrolysis of dissolved Al\(_2\)O\(_3\) in cryolite based molten fluorides, carbon anodes are still the choice for the electrolysis of solid metal oxides in molten CaCl\(_2\). To deal with the relevant problems, recently we have proposed a “disengaging strategy” by electrolysis of solid metal oxides in MgCl\(_2\) based molten salts, in which the solubility of \(O^{2-}\) ions is insignificant to transport \(O^{2-}\) to the anode.\(^13\) Alternatively, the released \(O^{2-}\) ions stay in the cathode by forming MgO precipitation, and the anode reaction is thus changed to oxidation of Cl\(^-\) ions to the Cl\(_2\) gas. This disengaging strategy makes the carbon anode effectively non-consumable, eliminating \(CO_2\) emission and all related problems. Our new process can be represented by Reactions (4–6).

Overall reaction:

\[ \text{MO}_x + x\text{MgCl}_2 = \text{M} + x\text{MgO} + x\text{Cl}_2 \]  

(4)

Cathodic reaction:

\[ \text{MO}_x + x\text{MgCl}_2 + 2xe^{-} \rightarrow \text{M} + x\text{MgO} + 2x\text{Cl}^- \]  

(5)

Anodic reaction:

\[ 2x\text{Cl}^- \rightarrow x\text{Cl}_2 + 2xe^{-} \]  

(6)

As indicated in Table 1, this new process, thermodynamically, can be applied to reduce most transitional metal oxides to respective metals, including some rare earth metals, such as uranium.

Considering molten MgCl\(_2\) by itself has a relatively high vapor pressure, it is better to be used together with other chloride salts, such as NaCl and KCl. Using
A mix of molten salts can also further decrease the solubility of MgO. The solubility of MgO in pure MgCl₂ at 730 °C was reported to be about 0.36 mol%, which is fairly low in contrast with CaCl₂ (>20 mol% at 850 °C) and LiCl (>10 mol % at 650 °C). However, if 70 mol% NaCl was added, the solubility of MgO can be significantly decreased to about 0.01 mol%. On the other hand, the solubility of MgO in equimolar NaCl–KCl at 730 °C is also less than 0.01 mol%. These data suggest that using the molten mixture of MgCl₂–NaCl–KCl (MNK) can be more effective for disengaging the carbon anode from O₂⁻ ions.

In this work, we further demonstrate our new process by the electrolysis of Ta₂O₅ in the MNK melt at 700 °C. The mechanism of Ta₂O₅ reduction was investigated, and nanometer Ta powder (<50 nm) was produced at an energy consumption of about 1.0 kW h kg⁻¹ Ta. The inert graphite anode was confirmed with the anodic gaseous products analysed in detail.

### Experimental

Anhydrous MgCl₂, NaCl, and KCl (analytical grade, Tianjin Guangfu Fine Chemical Research Institute, or Sinopharm Chemical Reagent Co., Ltd, China) were mixed in the eutectic ratio 5 : 3 : 2 (in mole ratio and 5 mol in total amount), and heated in a graphite or alumina crucible (inner diameter: 25–50 mm; height:

200–700 mm) in a programmable vertical furnace equipped with a sealable stainless steel retort (Wuhan Experimental Furnace Plant). The furnace temperature was slowly raised to and maintained at 400 °C for more than 12 h, and then to 700 °C until the salt mixture was fully molten. Pre-electrolysis of the molten salt was applied at 1.6 V to remove moisture and other redox-active impurities with the graphite crucible (or a graphite rod of 10 mm diameter in the alumina crucible) as the anode and a Mo wire (diameter: 2 mm) as the cathode. Pre-electrolysis lasted (ca. 10 h) until the current reached a low and stable background level.

Cyclic voltammograms (CVs) were recorded using a Mo cavity electrode (MCE) loading with Ta$_2$O$_5$ powder, with the potential reference to a quartz sealed Ag/AgCl electrode. For constant potential, constant cell voltage and galvanostatic electrolysis, Ta$_2$O$_5$ powder (analytical grade; particle sizes: 300 nm; Zhuzhou Cemented Carbide Works Imp. & Exp. Company) was individually die-pressed into cylindrical pellets (10 MPa, 13 or 20 mm in diameter, 0.7–2 g: 1.1–1.7 mm in thickness, porosity: ~50%), sintered in air at 1000 °C for 2 h, and sandwiched between two molybdenum (Mo) meshes to form an assembled cathode. After electrolysis for a designated time, the cathode was removed from the furnace, cooled in argon, washed in distilled water, or in dilute HCl (0.1 mol L$^{-1}$) and water again, and then dried in a vacuum at 80 °C before further analyses. The CVs were recorded using CHI660A Electrochemical System (Shanghai Chenhua, China), while the electrolysis was controlled by a multichannel four-electrode potentiostat (Neware, China).

The products were characterised by X-ray diffraction spectroscopy (X-ray 6000 with Cu Kα1 radiation at λ = 1.5405 Å, Shimadzu, Japan), and a FEI Sirion Field Emission Gun SEM system. GC (FULI 9790II, with a thermal conductivity detector and argon serving as a carrier gas) was used for the analysis of the anodic gaseous products. Ion Chromatography (IC) analysis for Cl$^-$ ions was carried out using METROHM 881 Compact IC pro, with the ClO$_2^-$ ions reduced to Cl$^-$ ions by H$_2$O$_2$.

Results and discussion

Fig. 1 shows the cyclic voltammogram (CV) of Ta$_2$O$_5$ powders in MNK at 700 °C using the metallic cavity electrode (MCE). For comparison, a CV recorded on an empty MCE is superimposed. No significant reaction current can be observed on the blank CV before Mg deposition (C0) and dissolution, with an Mg/Mg$^{2+}$ equilibrium potential of about −1.55 V vs. Ag/AgCl. The reduction current of Ta$_2$O$_5$ was found initially to be −0.4 V vs. Ag/AgCl. Preliminary comparison and analysis of the CVs of Ta$_2$O$_5$ in molten MNK and those previously reported in CaCl$_2$ have revealed fairly similar main reduction features, showing mainly three reduction processes (C1–C3). However, the starting potential of C3 is unclear due to the overlap with C2.

According to Table 1, the reduction of Ta$_2$O$_5$ to Ta could occur at a potential about 0.9 V more positive than the deposition of Mg, thus, potentiostatic electrolysis of Ta$_2$O$_5$ was performed at −0.8 V vs. Ag/AgCl, a potential 0.75 V more positive than the Mg deposition potential so Ta was predicted to be produced. The current–time plot is shown in Fig. 2a. The reduction current rises initially to a peak suggesting the reduction followed the propagation of the three-phase interlines, which was generally observed during reduction of insulating oxides to metals.
In line with the CV, Fig. 2a also shows several reduction processes. The first reduction displayed a high reduction current of about 0.25 A in the initial 30 minutes. The second reduction corresponded to the plateau current at about 0.1 A, which began to decrease at about 110 minutes, then a slope change at about 250 minutes could indicate a third reduction process. Finally, the current levelled off to background current after 500 minutes. To identify these reductions, XRD patterns of the electrolysis products after different times were scanned and displayed in Fig. 3. It can be seen that after 27 minutes, the Ta₂O₅ was almost completely reduced to TaO₂. The electrolysis product at 300 minutes included Ta and Mg₄Ta₂O₉. The appearance of Mg₄Ta₂O₉ after TaO₂ may suggest the possible disproportionation reaction of TaO₂, possibly like its congener VO₂, and the generation of an excess of MgO may have shifted the reaction to form the stabilized Mg₄Ta₂O₉. The final electrolysis product after washing with water consisted of Ta and MgO. The presence of MgO in the cathode indicates its low solubility in the MNK melts as discussed above.

The cell voltage (the inset in Fig. 2a) during the −0.8 V constant potential electrolysis was also monitored. In the main reduction stage of Ta₂O₅, the cell
voltage was about 1.9 V, which was reasonably higher than the decomposition voltage \(~1.64\) V of Ta$_2$O$_5$ in the MgCl$_2$ based melt as calculated in Table 1. In addition, it can be seen that after the cell voltage decreased to about 1.64 V, it dropped suddenly. These may indicate that the electrolysis was mainly via the assumed Reaction (4) or specifically Reaction (7) for Ta$_2$O$_5$:

$$5\text{MgCl}_2 + \text{Ta}_2\text{O}_5 \rightarrow 2\text{Ta} + 5\text{MgO} + 5\text{Cl}_2(\text{g})$$  \hspace{1cm} (7)

Constant cell voltage electrolysis at 2.0 V was also carried out, and the current-time plot is shown in Fig. 2b. It can be seen that the reduction completed in about 50 minutes, and the dimensions of the cathode pellet remained almost unchanged before and after the reduction (Fig. 4a), suggesting the possibilities of both high electrolysis speed and high Ta recovery (nearly 100% in this work). Mass analysis was carefully carried out after the product was washed with water and 0.1 mol L$^{-1}$ HCl respectively, and this confirmed that most of the MgO

![Fig. 3](image_url) XRD patterns of the products collected at the indicated times of potentiostatic electrolysis (\(-0.8\) V vs. Ag/AgCl, water washed only) and constant voltage electrolysis of Ta$_2$O$_5$ (2.0 V, water and acid washed) at 700 °C in MNK.

Fig. 4 (a) Ta$_2$O$_5$ pellet collected after 80 min electrolysis in 700 °C MNK at 2.0 V. (b) Scanning Electron Microscopy (SEM) image of the Ta nanoparticles shown in (a) (after acid washing).
generated through Reaction (7) stayed in the cathode. It is interesting that although the porosity of the Ta₃O₅ pellet was only about 50% of that which is commonly used for electro-reduction in molten CaCl₂, the influence of MgO accumulation in the oxide cathode was insignificant for the electro-reduction. However, it can be derived that the porosity of the Ta₂O₅ cathode needs to be higher than 30% to prevent the ion passages from becoming blocked.

On the other hand, although the cathode pellet taken out from the molten salt was perfectly strong, it dispersed to a powder after washing in water. After being further washed with acid, pure Ta was obtained, and the XRD pattern is shown in Fig. 3. The SEM images show very fine particles (~50 nm) of the resulting Ta powder, which were smaller than those produced in molten CaCl₂ at 900 °C, suggesting higher specific capacitance.¹⁹ This phenomenon may be partly associated with the relatively low molten salt temperature (700 °C) and also partly attributed to the MgO precipitated inside the pellet which prevented physical sintering of the Ta particles. The current efficiency was higher than 92%, with an energy consumption of about 1.3 kW h kg⁻¹Ta for the electrolysis of 0.7 g Ta₂O₅ and 1 kW h kg⁻¹Ta for the electrolysis of 2 g Ta₂O₅.

On the graphite anode, for verification of chlorine evolution, galvanostatic electrolysis of Ta₂O₅ at 1.5 A was performed in MNK. Since the MNK melt does contain some O²⁻ ions, although with a concentration in the order of 10⁻⁴ in molar fraction, the discharge of O²⁻ ions on graphite would occur. According to Scheme 1, the amounts of O₂, CO₂, CO and Cl₂ in the anodic gaseous product were determined.

First, about 500 mL of anodic gas was collected as shown in Fig. 5a. The colour of the anodic product was yellowish green. This is straightforward evidence for formation of Cl₂ on the anode. After being absorbed by NaOH solution, a starch iodide test indicated the existence of ClO⁻ in the solution, again convincing evidence for anodic Cl₂ gas, which has been reacted with NaOH. In addition, ion chromatography (IC) analysis indicated that the Cl⁻ and ClO⁻ ion concentration in the NaOH solution approximately matched the absorbed gas volume (about 460 mL). About 40 mL colourless gas remained, and GC analysis (Fig. 6) indicated the existence of O₂ and CO with concentrations in the total anodic gas of about 1.2 mol% and 0.2 mol%, respectively.

Scheme 1  Illustration of the method for identification of anodic gas.
No CO₂ was detected by GC, however, even if it was formed on a graphite anode, according to the Cl₂ volume indicated by IC, the CO₂ concentration would be very low. Similarly, it was reported that no CO₂ gas was found as an anodic product during electrolysis of MgO in MgCl₂–NdCl₃ system at 700 °C.²¹ However, it seems strange that there was O₂ as an anodic product without CO₂ gas on a graphite anode. For confirmation, we designed another experiment. As shown in Scheme 1b, the anodic gaseous product was allowed to react with the reducing Fe powders thoroughly, and the remaining colourless gas was also detected by GC. According to Fig. 6, CO₂ was in truth absent in the anodic product.

According to the above tests, the composition of the anodic gaseous product during galvanostatic electrolysis of Ta₂O₅ at 1.5 A consisted of mainly Cl₂ gas, about 1 mol% O₂ gas and trace amounts of CO gas, as summarized in Table 2. No CO₂ was formed on the graphite anode.

To determine the origination of anodic O₂ gas, CVs of the graphite electrode in the MNK melt were recorded as shown in Fig. 7. According to Fig. 7, the evolution...
of chlorine \((a_0)\) was initiated at 1.1 V vs. Ag/AgCl. Coupled with the deposition potential of Mg (see Fig. 1a) on MCE, the decomposition voltage of MgCl\(_2\) was determined to be 2.65 V, which is fairly close to the thermodynamic value (2.534 V) calculated from HSC Chemistry 6. The measured value was slightly higher, which is reasonable considering that the molar fraction of MgCl\(_2\) in the MNK was only 0.5. The current corresponding to chlorine evolution increased rapidly with the positive scan, indicating that there is no kinetic difficulty on the discharge of Cl\(^-\)/C\(_0\) ions on a graphite anode. Since Cl\(^-\)/C\(_0\) ions are the main anions in the MNK melt, concentration polarization for the chlorine evolution is also negligible. On the contrary, in molten CaCl\(_2\), the anodic discharge of O\(^2^-\)/C\(_0\) ions on graphite is well known to be kinetically difficult both in terms of charge transfer and mass transfer.

Before \(a_0\), there is an apparent anodic current at \(a_1\), which is very stable according to the multi-cycle scans and could be attributed to the discharge of O\(^2^-\) ions on the graphite anode. However, unlike the discharge of O\(^2^-\) on a carbon based anode in molten CaCl\(_2\), which exhibited complicated voltammograms involving formation of CO\(_2\), CO and O\(_2\) gases,\(^{22-24}\) here the CVS of O\(^2^-\) discharge in MNK featured a single reaction, probably the formation of O\(_2\) gas as mentioned above. To confirm it, potentiostatic electrolysis was performed at 1.0 V vs. Ag/AgCl against a Ta\(_2\)O\(_5\) pellet cathode. The anodic current remained very stable at about 15 mA during the total 3 hour electrolysis. However, no anodic gas has automatically flowed out from the anodic gas chamber. The chamber was then sealed and the anodic gas was sampled at different times for GC analysis.

**Fig. 7** Cyclic voltammogram of graphite in eutectic MgCl\(_2\)–NaCl–KCl (700 °C) vs. Ag/AgCl, scan rate 200 mV s\(^{-1}\).
Fig. 8 shows the GC analysis results. As can be seen, after 0.5 h electrolysis, there was a small peak of O₂ gas but no CO and CO₂ gas was found. After about 1 h electrolysis, the O₂ concentration increased significantly, and small peaks of CO and CO₂ became just perceptible, and the O₂ : CO : CO₂ ratio was about 8.2 : 1.3 : 0.5, which changed to 7.9 : 1.0 : 1.1. Considering initially there is only O₂ evolution and the CO₂ content became larger and larger, it is likely that the formation of CO₂ is a result of a reaction between the graphite anode and the accumulated O₂ in the anodic chamber. Combining the CV result and the GC analysis of the anodic gas during constant potential electrolysis at 1.0 V, it might be reasonable that the a1 current in Fig. 7 corresponds to the discharge of O²⁻ ions to O₂ gas on the graphite anode in the MNK melt at 700 °C. However, the small steady current (15 mA) at 1.0 V vs. Ag/AgCl was most likely to be the limited diffusion current of O²⁻ ion discharge, which is only about 1.5% of the total current considering a 1.0 A g⁻¹-Ta₂O₅ or higher current would be applied in the actual electrolysis.

The optical images of the graphite anode before and after repeated electrolysis for ca. 100 h in the eutectic MNK melt were compared in Fig. 9. In line with the Cl₂ and O₂ gas evolution at the anode, the fine spiral machining marks of ca. 100 nm in width on the side of the graphite rod remained almost intact, even though these protruding parts are usually the most vulnerable sites to chemical or electrochemical attack. These observations suggested that the graphite anode is basically inert during the electrolysis of solid oxide cathode in the MgCl₂ based molten salts. However, it is well-known that the anodic reaction of the solid oxide cathode electrolysis at a graphite electrode in CaCl₂ was the discharge of the O²⁻ to carbon oxides and carbonate ions, leading to significant erosion of the graphite anode, shuttle reactions of the oxygenated species (O²⁻ and CO₃²⁻), and formation of a thick layer of floating carbon powder on the surface of the molten electrolyte. Since there was no corrosion to the graphite anode and consequently no carbon generated on the cathode due to the reduction of CO₃²⁻ in a MgCl₂ based electrolyte, no floating carbon was supposed to form on the surface of molten MNK. This was confirmed by the clear surface of MNK after 100 h electrolysis of Ta₂O₅ as shown in Fig. 9c.
These results indicate that both the graphite anode and the MNK salt are ready for lengthy electrolysis. Of course, the consuming MgCl₂ needs to be supplemented, for example, along with the metal oxide pellet. In addition, the Cl₂ gas has many applications and can be collected as already commercially demonstrated in the chlor-alkali industry and the electrolysis of molten LiCl and MgCl₂. It is also possible to use the Cl₂ gas to regenerate MgCl₂, noting the recent progress in developing H₂–Cl₂ fuel cells, which generate electricity and HCl while HCl is needed to convert MgO in the cathode back to MgCl₂.

Conclusions

We have demonstrated the high speed, low energy consumption electrolysis of Ta₂O₅ in MgCl₂–NaCl–KCl melt using an inert graphite anode. The reduction process was investigated by cyclic voltammetry, and potentiostatic and constant voltage electrolysis. The main intermediate products of the electro-reduction of Ta₂O₅ were identified to be TaO₂ and Mg₄Ta₂O₉. The final reduction product was nanometer Ta powder with sizes of about 50 nm. The anodic product included mainly Cl₂ gas, plus about 1 mol% O₂. There was only about 0.2 mol% CO in the anodic gas, and no CO₂ was detected, suggesting that the graphite anode is fairly stable in our new process. The process should be applicable for the preparation of many other metals and alloys with high energy efficiency and low carbon emission.
