Abstract: The molecular interactions between the Ce(IV)-substituted Keggin anion \([PW_{12}O_{40}]^3−\) (CeK) and hen egg white lysozyme (HEWL), was investigated by molecular dynamics (MD) simulations. We compared the analysis of CeK with the Ce(IV)-substituted Keggin dimer \([PW_{11}O_{36}]_{2}^2Ce\) (CeK2) and the Zr(IV)-substituted Lindqvist anion \([W_{12}O_{42}]Zr(OH)_{2}(OH)]^3\) (ZrL) in order to understand how POM features such as the shape, the size, the charge or the type of incorporated metal influence the POM–protein interactions. Simulations revealed two regions of the protein, in which the CeK anion interacts strongly: the cationic sites formed by Arg21 on one hand and by Arg45 and Arg68 on the other. The two sites can be related with the observed selectivity in the hydrolytic cleavage of HEWL. The POMs chiefly interact with the side chains of the positively charged (arginines and lysines) and the polar uncharged (tyrosines, serines and asparagines) residues via electrostatic attraction and hydrogen bonding with the oxygens of the POM framework. The CeK anion shows higher protein affinity than the CeK2 and ZrL anions, because it is less hydrophilic and it has the right size and shape for stabilising interactions with several residues simultaneously. The larger and more negatively charged CeK2 anion has a high solvent-accessible surface, which is suboptimal for the interaction, while the smaller ZrL anion is highly hydrophilic and it cannot interact simultaneously with several residues so efficiently.

Introduction

Polyoxometalates (POMs) are a versatile and tunable class of inorganic polynuclear metal-oxygen clusters.\[12\] These metal complexes are built up from oxo-bridged early transition metals in their highest oxidation state, most notably Mo, W and V. The removal of a W=O unit from the plenary structure of the POMs generates anionic lacunary species that can coordinate a diversity of metal ions. This expands the variety of POM structures, resulting in their application in the fields of catalysis,\[8\] material science\[4\] and medicine.\[5\] The metal substitution provides a custom-made coordination chemistry and reactivity with catalytic applications ranging from alkene epoxidation by group IV-substituted POMs\[6\] to the splitting of water by Ru- and Co-substituted ones.\[7\] More interesting in this context is their biological activity, which includes in vitro and in vivo anticancer, antiviral and antibiotic activity.\[5\] POMs can also interact with proteins causing enzyme inhibition activities.\[8] For years, Yonath et al. have used polyoxometalates as "super-heavy atoms" in the crystal structure determination of ribosome.\[9\] Although little is known about the exact molecular mechanism responsible for POM biological activity, the importance of the polyoxometalate size, shape and charge, as well as the kind of incorporated metal ion has been recognized.

In recent years Parac-Vogt et al. have studied the POM hydrolytic activity towards the highly inert peptide bond in biomolecules such as dipeptides and oligopeptides,\[10\] and more importantly, reported the first examples of selective hydrolysis of proteins by POMs.\[11,12,13\] The active POMs include different structures of Ce(IV)- and Zr(IV)-substituted anions, which initially were applied to the hydrolysis of hen egg-white lysozyme (HEWL)\[11\] and more recently to human serum albumin (HSA).\[12\] and myoglobin.\[12\] It was observed that the peptide bond cleavage sites are close to positively charged protein surface patches. Therefore, it was postulated that the electrostatic interactions with the negatively charged POM structures lead to the selective hydrolysis in an enzyme-like recognition scheme.\[11,15\] Nevertheless, so far no direct proof for the electrostatic nature of these POM…protein interactions has been presented.

Understanding the physicochemical foundations of the interactions between POMs and biomolecules might have important implications for medical and biochemical applications of POMs beyond selective peptide hydrolysis. In this regard, computational simulations could facilitate the understanding of the molecular properties that govern the interaction in order to further develop metal-substituted POMs with specific interaction properties. Although these tools have been largely employed to study POM chemistry,\[16\] the study of POM-protein interactions at molecular level is still a largely unexplored area.

There have been a number of docking studies exploring the binding locations for POMs with proteins, but due to the intrinsic limitations of this methodology little was revealed about the driving forces that are responsible for the specific interactions.\[16\] These studies proposed that POMs interact mainly with positively charged amino acids such as Lys, His or Arg, or with polar uncharged ones such as Asn, Ser, Cys, Thr or Gin. For example, Hill et al. showed that Nb-containing POMs inhibit HIV-1 protease by binding to a cationic pocket of lysine residues away from the active site.\[17\] Similar findings were derived from experimental studies, which identified electrostatic effects as the main factor in the interaction of POMs with biomolecules based on luminescence of Eu-substituted POMs, the fluorescence of
FULL PAPER

Tryptophan residues, isothermal titration calorimetry (ITC), and NMR and circular dichroism (CD) spectroscopy.\textsuperscript{[11],[12]} For example, Qu et al. proposed that POMs bind to the positively charged His13-Lys16 cluster region of amyloid β-peptides associated with Alzheimer’s disease.\textsuperscript{[18]} It was also observed that the POMs can bind sufficiently tightly to cause structural change in basic fibroblast growth factor (bBGF).\textsuperscript{[19]} More specifically, recent studies using model amino acids and peptides attributed the mechanism of interactions with biomolecules to electrostatic interactions and hydrogen bonds between amino acids and the negative charges of POMs.\textsuperscript{[19]}

Interestingly, Qu et al. found an apparent trend related to POM composition: the larger negative charge, the higher the binding affinity, and the stronger the inhibitory effect.\textsuperscript{[18],[20]} However, if one considers the charge density of the anion instead of the overall charge, the inactive POMs are not only the least charged but also the smallest anion carrying one of the highest charge densities among the series. Thus, we suspect that binding might require cooperation of electrostatic (high negative charge) and hydrophobic (accessible surface) forces. Moreover, hydrophobic and electrostatic interactions in the most general sense are non-specific effects that would not explain by themselves the specificity of interaction sites, the selective enzyme-like recognition, nor the dependence on POM size and shape. Therefore, we believe that it is necessary to analyse the factors underlying the interaction of POMs with biomolecules beyond size-specific electrostatic effects in order to obtain a full picture of the physicochemical foundations in these processes. Herein, we performed molecular dynamics (MD) simulations of three different POM structures with HEWL in aqueous solution. The three POMs are Ce-substituted Keggin-type anion [PW\textsubscript{11}O\textsubscript{39}Ce(OH)\textsubscript{3}]	extsuperscript{3}\textsuperscript{-} (CeK), [Ce(PW\textsubscript{11}O\textsubscript{39})\textsuperscript{2}\textsuperscript{-} (CeK\textsubscript{2}) and [W\textsubscript{18}O\textsubscript{49}Zr(OH)\textsubscript{2}(OH)]\textsuperscript{2}\textsuperscript{-} (ZrL).

![Figure 1. Polyhedral representation of the anions [PW\textsubscript{11}O\textsubscript{39}Ce(OH)\textsubscript{3}]\textsuperscript{3}\textsuperscript{-} (CeK), [Ce(PW\textsubscript{11}O\textsubscript{39})\textsuperscript{2}\textsuperscript{-} (CeK\textsubscript{2}) and [W\textsubscript{18}O\textsubscript{49}Zr(OH)\textsubscript{2}(OH)]\textsuperscript{2}\textsuperscript{-} (ZrL).](image)

The systems were simulated by classical MD using the GROMACS 4.5.4 software\textsuperscript{[21]} and the AMBER99 force field,\textsuperscript{[22]} which has been successfully employed to study the aggregation behaviour of POMs in solution by Chaumont and Wipff.\textsuperscript{[23]} The potential energy U is empirically described by a sum of bond, angle, and dihedral deformation energies (bonding terms) and pair-wise additive 1-6-12 (electrostatic and van der Waals, non-bonding terms) interactions between non bonded atoms. The parameters for the Ce-substituted POMs were obtained following the procedure of Bonet-Avalos, Bo, Poblet et al.\textsuperscript{[24]} We used CHELPG atomic charges derived from the electrostatic potential. They were obtained with the Gaussian09 package\textsuperscript{[25]} at the DFT level (BP86 functional),\textsuperscript{[26]} using the LANL2DZ basis set\textsuperscript{[27]} for W, O and H atoms, and the MWEB8 basis set\textsuperscript{[28]} for Ce. Solvent effects were included in geometry optimizations by using the IEF-PCM model\textsuperscript{[29]} as implemented in Gaussian09 package.\textsuperscript{[30]} The set of Lennard-Jones parameters for W and O atoms were taken from previous work,\textsuperscript{[31]} and those for Ce were taken from UFF force field.\textsuperscript{[32]} Parameters for ZrL were taken from previous studies.\textsuperscript{[33]} The geometry of the 8+ charged HEWL was taken from protein data bank (PDB) database (PDB ID: 3JUV).\textsuperscript{[34]} For the MD simulations with CeK, the protein was embedded in a water solvent box of dimensions 73.1 × 68.8 × 77.1 Å, one POM molecule (q = -3) and five chloride ions to neutralize the system. MD simulations with ZrL were performed in a water solvent box of dimensions 75.7 × 78.4 × 79.1 Å, one POM molecule (q = -3) and five chloride atoms to neutralize the system. For simulations with CeK\textsubscript{2} the size of the box was 75.7 × 78.4 × 79.1 Å for the runs starting at the vicinity of protein site I and 73.1 × 68.8 × 77.1 Å for those of site II. One POM molecule (q = -10) and two Na\textsuperscript{+} ions were added to neutralize the system. Water was represented with the TIP3P model.\textsuperscript{[35]} All simulations were performed with 3D-periodic boundary conditions using an atom cutoff of 14 Å for 1-4 van der Waals and of 10 Å for 1-4 Coulombic interactions and corrected for long-range electrostatics by using the particle-particle mesh Ewald (PME) summation method.\textsuperscript{[36]} The simulations were performed at 300 K starting with random velocities. The temperature was controlled by coupling the system to a thermal bath using the Berendsen algorithm\textsuperscript{[37]} with a relaxation time of 0.5 ps to keep the NVT microcanonical conditions throughout the simulation. Newton equations of motion were integrated using the leap-frog algorithm,\textsuperscript{[38]} and a time step of 1 fs. The bonds with hydrogens were restrained using the LINCS algorithm.\textsuperscript{[39]} Starting either at the vicinity of site I or site II, we run 5 independent simulations of 20 ns for each POM at each site. Before the production runs, the systems were equilibrated...
Results and Discussion

1. MD study of $[\text{PW}_{11}\text{O}_{39}\text{Ce(OH)}_{2}]^{3-}$ anion with HEWL in solution.

Initially, we simulated the monomeric Ce-substituted Keggin-type anion $[\text{PW}_{11}\text{O}_{39}\text{Ce(OH)}_{2}]^{3-}$ (CeK) with HEWL in aqueous solution. Experimentally, the 1:2 dimeric structure $[\text{Ce(PW}_{11}\text{O}_{39})_{2}]^{10-}$ (CeK$_2$) was in fact the complex employed in the selective hydrolysis. However, this species is a highly unlikely catalyst because the coordination sphere of Ce(IV) is fully saturated by coordination to oxygen atoms of the POM framework. Since hydrolysis requires the binding of the Ce metal acting as a Lewis acid to the amide carbonyl, it was proposed that the interaction with protein induces dissociation of the dimeric species CeK$_2$ to the monomeric CeK POM. Some posterior evidence has supported this hypothesis. The analogous EuK$_2$ dimer was shown to dissociate leading to monomeric EuK, which is able to bind to amino acids. Similarly, when the analogous Zr dimer ZrK$_2$ was used for codissolution with HEWL, the resulting crystal structure showed exclusively the presence of the Zr-substituted monomeric species, ZrK.

For all the runs performed the interaction between the CeK anion and the HEWL is appreciable and remains present during most of the simulation time with non-bonding interaction energies averaging $-178$ kJ·mol$^{-1}$ for site I and $-161$ kJ·mol$^{-1}$ for site II (see Fig. 2 and Fig. S1 and S2 in Supporting Information). As a general trend, as the interaction with the protein strengthens, the solvent interaction energy lowers because the CeK anion has to remove the solvation shell to access protein surface. This can be seen in Fig. 2, where blue and red lines represent protein and solvent interaction energies, respectively. The graphs in Fig. 3 show the most strongly interacting amino acid is Arg21; the interaction is present during the whole 100 ns sampling. Then the CeK anion can interact with Ser100 and with either amino acids on the left- or the right-hand side of the entrance channel (Lys96 and Lys97 or Tyr23, respectively). Fig. 4 shows a
In the simulation at the vicinity of site II, the CeK anion adsorbs onto the protein's surface, interacting directly with the amino acids of cleavage site II, which are exposed to the solvent in the β-strand region. In fact, the most strongly interacting amino acid in this set of simulations is Arg45 belonging to cleavage site II (see Fig. 3, lower panel). This interaction persists for most of the simulation, and some additional ones can occur simultaneously with amino acids such as Arg68, Tyr53, Thr43 and Thr51 (Fig. 3, lower panel) that contribute to the stability of the CeK···HEWL complex. Fig. 7 shows an illustrative snapshot in which this additive interaction can be observed: strong interaction with positively charged amino acids Arg45 and Arg68 at different protein regions, and with polar amino acids Tyr53, Thr43 and Thr51. In both cases, the CeK anion interacts mostly through the POM framework, with the hydrophilic Ce(H₂O)₆ moiety pointing towards the solvent. The binding sites and the orientation of CeK anion revealed by dynamic simulations fully agree with the positions of the Zr-substituted Keggin-type anions co-crystallized with HEWL.[19]

As illustrative snapshots in Fig. 5, 6 and 7 show, the CeK anion can be in direct contact with the protein surface forming hydrogen bonds with the amino acids side chains through the most basic oxygen atoms of the POM framework. Several amino acids of different sections of the protein structure interact simultaneously with the anion in an additive manner, and both the terminal and the bridging oxygen atoms act as hydrogen acceptors. For example in the first snapshot of site I (Fig. 5), the side chains of Ser100 and Tyr23 form hydrogen bonds with the terminal oxo groups of the POM framework (O-H···O⁻ distances = 2.23 and 1.96 Å, respectively), while for positively charged Arg21 we observe an electrostatic contact. In the other snapshot of site I (Fig. 6), the CeK anion forms a double-hydrogen bonding interaction with two of the guanidinium N-H groups of Arg21 involving a bridging oxygen of POM framework. The NH₄⁺ amino group of Lys96 forms a hydrogen bond with the POM, whereas the analogous Lys97 is bound via an electrostatic-type interaction showing N-H···O⁻ distances < 10 Å. Similarly, for site II (Fig. 7), the CeK complexation occurs via multiple binding interactions such as hydrogen bonding with Thr43, Thr51 and Tyr53 (O-H···O⁻ distances ranging from 1.85 to 2.42 Å), and electrostatic with Arg45 and Arg68. Within these snapshots, the polar uncharged amino acids serine tyrosine, and threonine show computed interaction energies ranging from -37 to -47 kJ·mol⁻¹, which lie within the typical energy range for normal hydrogen bonds.[38] For the positively charged arginines and lysines, the obtained interaction energies are two-fold higher (ranging from -71 to -104 kJ·mol⁻¹) and lie in the range of typical strong hydrogen bonds, which include the positive charge assisted hydrogen bonding X-H···A.[38]

We have analysed the formation of hydrogen bonds along the whole simulation in more detail. Fig. 3 shows the simulated
hydrogen bond persistences as a percentage of the trajectory (lines). For each residue we quantified the number of snapshots showing H-bonding to CeK whose value was normalized by the total number of snapshots and used as representation of the overall CeK···HEWL H-bond statistics. The H-bond criteria comprise a distance (<3.5 Å) and an angle (X-H-O_COM > 130°) constraint. This parameter provides information on the most strongly interacting amino acids and the nature of their interaction, complementing the average energies reported in Fig. 3. The longest-lasting and the strongest interactions are with Arg21 for site I and Arg45 and Arg68 for site II. This agrees with previous NMR results showing resonance shifts for arginine side chains in the presence of POM. The interaction with these amino acids combines electrostatic and hydrogen-bonding contributions. For example although the interaction with Arg21 is present during the whole simulation (see Fig. S3), the persistence represents only 57%. The affinity of the CeK anion increases by additional hydrogen bonding with the side chains of Ser100 and Tyr23 in site I and Thr53 and Thr43 in site II, with percentage persistence ranging from 20 to 40%. We could also identify other non-polar amino acids, such as glycine and alanine that interact appreciably with the CeK, via the N-H amide group, the most outstanding being Gly102 and Gly104 with percentage persistence between 10 and 20% (see Fig. 3). It should be noted that although it had been proposed that hydrogen-bonding might be an interaction force in POMs binding to biomolecules, this is the first time that these interactions have been quantified.

Figure 7. Illustrative snapshot of CeK···HEWL interaction at the vicinity of site II taken at 18870 ps of run 1 (interaction energy -313 kJ·mol$^{-1}$). Left panel highlights interacting amino acids and cleavage site II (Asn44 and Arg45). Right panels: closer look at the interaction between CeK and amino acids Arg45, Arg68, Tyr53, Thr43 and Thr51 (-77, -93, -46, -39 and -39 kJ·mol$^{-1}$). Distances in Å.

In the crystal structure, the Zr-substituted [PW$_1$O$_{12}$Zr(OH)$_6$]$_4^-$ anions showed direct hydrogen-bond interactions with HEWL, and also, water-mediated interactions, in which a layer of water molecules connected the CeK anion and the protein. There are other X-ray structures in which the interactions between the POMs and the protein are partially mediated by the solvent. For example, the octamolybdate and the hexatungstotellurate anions interact partially via water molecules with uncharged polar amino acids such as glutamine and threonine in the molybdenum storage protein and abPP04 mushroom tyrosinase, respectively. Since the interaction of the POM with the solvent decreases as the interaction with the protein increases, the optimal situation might be the water-mediated contact in which the CeK anion keeps the first solvation shell and there is still a non-bonding electrostatic interaction with the positively charged amino acids. Fig. 8 presents a sequence of snapshots taken during the approach of CeK anion to site II as illustrated by the evolution of interaction energies in Fig. 2. In the frames of Fig. 8, we can observe different water-mediated interactions with Arg45, Arg68 and Thr43; and how the successive removal of the water layer surrounding the POM reduces the CeK···water interaction energy, which is balanced by the increase of the direct contact with the protein residues. Overall, both experiments and simulations indicate that electrostatic-based water-mediated interactions are quite favourable. However, in the dynamic process the CeK anion can easily remove the solvation shell to reach the protein surface, stabilized via hydrogen bonding with polar and positively charged amino acids. Analogously, other X-ray structures have shown that the POMs are also able to interact directly with the protein. Rompel et al. have crystallized HEWL with the Anderson-Evans-type hexatungstotellurate [TeW$_6$O$_{39}$]$^6^-$ anion which binds to positively charged (Arg and Lys) or polar uncharged residues (Asn and Gin) similarly to CeK anion in our simulations. Interestingly, they identified a specific cationic site formed by Arg45 and Arg68 where the hexatungstate binds similarly to CeK at site II. Also the analogous anion $[\text{W}_6\text{O}_{39}\text{H}_6]^6^-$ binds NTPDase1 directly interacting with Lys, Asn and Gin.

Figure 8. Snapshots taken during the approach of CeK anion to protein site II. For clarity, only selected water molecules are shown. Distances in Å and energies in kJ·mol$^{-1}$.

The CeK anion interaction does not induce any conformational change in the HEWL structure and we only observed small geometrical differences in the side chains. This agrees with NMR studies indicating that HEWL structure was preserved upon binding to the analogous Keggin-type Zr-
substituted anion. Thus, for the available simulation times, we cannot expect to observe a direct interaction of CeK with site I (Trp28–Val29) site which would involve a modification of protein secondary structure. However, the observed binding site at Arg21 might be related to an entrance channel to the solvent-inaccessible site I via secondary structure decrease of the α-helix. For site II, the long and strong interaction with Arg45 is quite noteworthy because it belongs to the cleavage site II. As in the X-ray structure, the catalytically active Ce(IV) centre points towards the solvent due to the hydrophilicity of the Ce(IV)-aqua moiety. Consequently, the dynamic hydrolysis process should involve anion reorganization to bind the amide oxygen with the corresponding energy penalty. Nevertheless, the direct interaction of CeK to cleavage site II revealed in this study is consistent with the hydrolytic selectivity observed at Asn44-Arg45 bond.

2. Influence of POM structure on the POM···protein interactions.

To get further insight into how the metal ions and ligands can affect the interaction between POMs and proteins, we compared the behaviour of the CeK anion with the Ce(IV)-substituted Keeggin dimer [Ce(PW11O39)3– (CeK2), and the Zr(IV)-substituted Lindqvist anion, [ZrO2Zr(OH)2(OH)2]5– (ZrL)]. The dimeric CeK2 anion is in fact the species used for peptide hydrolysis, and it differs from CeK anion in that it carries greater negative charge and is larger and more extended. It also plausibly that the enzyme-like recognition of the POM occurs before the dimeric CeK2 species dissociates into CeK, and then interaction with protein promotes the hydrolysis of CeK2. The ZrL species represents a POM structure with smaller size and a different transition-metal substitution, which was also active towards the peptide bond hydrolysis in proteins. Moreover, in POM chemistry the charge/metal ratio parameter (q/M) has been used to set structure activity relationships because it reflects better charge distribution on the oxide structure. For the three selected POMs, the values are: 0.25 for CeK, 0.43 and 0.50 for CeK2 and ZrL, respectively.

Table 1. Comparison of the HEWL affinity of the three POMs: CeK, CeK2 and ZrL. Estimated from the percentage of POM···HEWL contact persistence, interaction strength during the contact and the non-binding interaction with the solvent per solvent-accessible atom. Energies in kJ mol−1.

[a] The values are quantified every 4 ps time frame over 100 ns MD trajectories.

Our simulations showed that POMs bind proteins mainly by electrostatic interactions; however we anticipated that the interaction with the solvent, as well as the size of the system allowing several interactions to occur simultaneously, also need to be considered. In fact, Nado et al. have recognized that the overall charge of the cluster is not the single parameter governing the binding process when comparing the binding of Human Serum Albumin (HSA) with POMs of different atomistic composition: [P2W7O40]16–, [Cu2P2W7O40]8–, [NiP2W7O40]8–, [H2W12O40]2– and [NaP2W7O40]2–. Table 1 compares the simulated percentage of POM···HEWL interaction persistence for the three POMs which reflects their binding affinity to the protein. We quantified the number of snapshots in which the POM is closer than 3.5 Å to the protein and normalized by the total number of snapshots. Roughly, the higher the charge density (q/M ratio), the lower the binding affinity of the POM, indicating that the less hydrophilic character of the anion might favour its protein affinity in water solution. In fact, the q/M ratio correlates with the computed POM solvation energies per solvent-accessible atom (Table 1), measured as the average non-binding interactions with the solvent when the POM is not in contact with the protein. The solvent-accessible atoms consist of the terminal and bridging oxygen atoms of the POM, and the ligands on the imbedded metal. Table 1 also compares the interaction strengths, measured as the average of POM···HEWL interaction energies when the POM is in contact with the protein (POM···HEWL distance < 3.5 Å). The CeK anion shows higher affinity for HEWL than CeK2 and ZrL anions. The highly hydrophilic and small ZrL anion exhibits shorter persistence values (56 and 69% for site I and II) compared to CeK because the solvation energy becomes higher while the interaction strength with HEWL remains similar (Table 1). The protein affinity of CeK2 anion lies in an intermediate situation with persistence values (90 and 95% for site I and II) closer to CeK anion. The computed solvation energy of CeK2 is significantly higher due to its hydrophilicity, which however, is partially balanced by the stronger interaction strength due to the increase of interactions with multiple residues (see below for more details).

Fig. 9 compares the average interaction energies of the POMs with the individual amino acids. For CeK2 and ZrL anions, the most strongly interacting residues are also Arg21, Lys96 and Lys97 for simulations at site I and Arg45 and Arg68 for simulations at site II. In general, the CeK2 anion shows the higher average interaction energies (green bars) than those for CeK anion (yellow bars) and much higher than those for ZrL (blue bars). Their interactions with the proteins involve mainly hydrogen bond-mediated direct contacts with the side chains of positively charged amino acids such as arginine and lysine, and polar ones such as serine and tyrosine (see Fig. 10 and 11 for representative interactions of CeK2 and ZrL). Therefore, these electrostatic interactions in the form of hydrogen bonding might be generalized in the binding of POMs to proteins, as recent review on the use of POMs in protein crystallography indicates.

Nevertheless among the POM series, we found remarkable differences on the extent, the strength and the type of interaction with protein that can be directly related to the POM composition.

In the simulation of CeK2 anion at site I, the POM interacts mainly with Arg21 as it was observed for CeK, but because of its greater size additional strong interaction appears with other amino acids such as Lys96 and Lys97 where the two Keggin units operate simultaneously (see Fig. 10 for representative snapshot). This makes the interaction strength significantly higher than that for CeK (~260 vs. -178 kJ mol−1 in Table 1). Interestingly, the additive effect of the two Keggin units can induce some structural changes in the protein. At the POM binding site, the protein structure opens leading to a more...
Figure 9. Comparison of amino acid specific POM···HEWL interactions for CeK (yellow bars), CeK₂ (green bars) and ZrL (blue bars) anions. Average non-bonding interaction energies in kJ·mol⁻¹ computed for snapshots taken every 4ps from the 100 ns of sampling.

accessible entrance channel to the cleavage site I (see Fig. 10, left). Fig. 12 shows that the root mean square deviation (RMSD) of the backbone portion involving the residues directly interacting with the POMs at site I (Tyr20, Arg21, Gly22, Tyr23, Lys96 and Lys97) is significantly larger for CeK₂ than for CeK and ZrL. This kind of conformational process might initiate a secondary structure decrease of the α-helical part required to expose the cleavage site I to the hydrolysis catalyst. In the case of the simulation of the CeK₂ anion at site II, the anion does not stay interacting with Arg45 as reflected in the low average interaction energy (Fig. 9). Instead, the anion is released into the solution and/or it moves through protein surface interacting with other cationic sites. Compared to interaction occurring at the vicinity of site I, here the topology of the protein does not allow CeK₂ anion interaction with the two Keggin units simultaneously. Consequently, the POM has a larger surface exposed to the solvent that pulls the whole POM towards the bulk of the solution. Thus, the interaction strength at site II (-224 kJ·mol⁻¹) is weaker than that of CeK₂ for site I (-260 kJ·mol⁻¹).

Figure 10. Illustrative snapshots of CeK₂···HEWL interaction at site I and II taken at 10494 ps of run I and 11924 ps of run1, respectively (interaction energies -408 and -283 kJ·mol⁻¹). Left panel highlights the most strongly interacting amino acids for simulation at site I: Arg21, Lys96 and Lys97 (-108, -86, and -120 kJ·mol⁻¹). Right panel highlights those for simulation at site II: Arg45 and Arg68 (-123 and -117 kJ·mol⁻¹). Distances in Å.

The interaction mode of ZrL anion with the protein resembles that of CeK; the basic oxygen atoms of the POM framework form hydrogen bonds and the Zr-substituted moiety mostly points towards the solvent (see Fig. 11). However, the persistence of the interactions is significantly shorter as reflected by the average interaction energies with individual residues in Fig. 9. The smaller size of the anion does not allow ZrL to interact simultaneously with several residues so effectively. For example in site I, the anion interacts alternatively with Arg21 and Lys97 jumping from one residue to the other. However, the interaction strength of ZrL (-168 kJ·mol⁻¹) is similar to that of CeK (-178 kJ·mol⁻¹) because the higher charge density of ZrL atoms can lead to stronger interactions with individual amino acids.

Figure 11. Illustrative snapshots of ZrL···HEWL interaction at the vicinity of site I and II taken at 40 ps of run I and 560 ps of run1, respectively (interaction energies -120 and -195 kJ·mol⁻¹). Left panel highlights the most strongly interacting amino acid for simulation at site I: Arg21 (-85 kJ·mol⁻¹). Right panel highlights those for simulation at site II: Arg45 and Arg68 (-69 and -114 kJ·mol⁻¹). Distances in Å.
Conclusions

In this work we report for the first time the use of molecular dynamics (MD) simulations to analyse the interaction between proteins and polyoxometalates by using the specific case of hen egg-white lysozyme (HEWL) and three different POMs including 1:1 and 1:2 Ce(IV)-monosubstituted Keggin POMs (CeK and CeK₂, respectively) and Zr(IV)-monosubstituted Lindqvist POM (ZrL).

In the MD simulations with the CeK anion, we have identified two sites of the protein in which the POM interacts strongly that can be related to the observed selectivity in hydrolytic activity of Ce(IV)- and Zr(IV)-substituted POMs towards the Trp28–Val29 (site I) and Asn44–Arg45 (site II) bonds. The CeK anion interacts strongly with Arg21 at an entrance channel to the cleavage site I buried in a hydrophobic pocket, and with Arg45 directly at site II. Both interactions occur through the POM framework with the catalytically active Ce(IV) centre pointing towards the solvent due to the hydrophilicity of its aqua ligands. This is in full agreement with the X-ray structures obtained from the recent co-crystallization of HEWL and a Zr-substituted Keggin-type POM. Thus, the modelling also established a relationship between the non-bonding electrostatic type interaction of the CeK anion with HEWL and the observed selectivity of the hydrolysis.

In general, the interaction of POMs with HEWL involves charge attraction and hydrogen bonding of the basic oxygen atoms of POM framework with the side chains of positively charged amino acids (arginine and lysine) and of polar uncharged amino acids (tyrosine, serine and asparagine). The formation of hydrogen bonding with the N-H amide group of the main protein chain is also plausible, although its extent is less important. Moreover, depending on the size and shape of the polyoxoanion the cooperative effects, in which several amino acids interact simultaneously with the oxide framework, are enhanced or decreased.

The protein affinity of the CeK anion is higher than for CeK₂ and ZrL anions. The Keggin-type CeK anion is less hydrophilic reducing the solvation energies and it has the right size and shape for accepting the additive effect of several amino acids simultaneously. The larger and more charged dimeric CeK₂ anion has more charge density and larger solvent-accessible surface that increases its hydrophilicity and reduces its affinity to proteins. However, the CeK₂ anion can interact very strongly with some sections of the protein through its two dimeric units at once, causing some structural changes in HEWL. They can include an opening of the entrance channel to cleavage site I that could expose the peptide bond to be hydrolysed. The smaller ZrL anion has high charge density that increases its hydrophilicity, and in addition, its size and shape do not allow interaction with several amino acids simultaneously so effectively causing the lowest protein affinity among the series of studied POMs. Thus, these simulations demonstrated that an optimal interaction POM···protein should balance charge and size. In addition, the study proves the feasibility of this computational approach, opening up new opportunities to study another range of other POM···protein interaction and other chemical processes.

Keywords: polyoxometalate • protein • molecular dynamics • DFT • peptide hydrolysis

The molecular interactions between polyoxometalates (POMs) and proteins have been described at atomic level by molecular dynamics simulations for the first time. We evaluated how POM features such as the shape, the size, the charge or the type of incorporated metal influence these interactions. The POM with the higher protein affinity is less hydrophilic and it has the right shape for establishing interactions with several residues simultaneously.
