Abstract

Learning to associate cues or contexts with potential threats or rewards is adaptive and enhances survival. Both aversive and appetitive memories are therefore powerful drivers of behaviour but the inappropriate expression of conditioned responding to fear- and drug-related stimuli can develop into anxiety-related and substance abuse disorders, respectively. These disorders are associated with abnormally persistent emotional memories and inadequate treatment, often leading to symptom relapse. Studies show that cannabidiol, the main non-psychotomimetic phytocannabinoid found in Cannabis sativa, reduces anxiety via serotonin1A and (indirect) cannabinoid receptor activation in paradigms assessing innate responses to threat. Accumulating evidence from animal studies investigating the effects of cannabidiol on fear memory processing also indicates that it reduces learned fear in paradigms that are translationally relevant to phobias and post-traumatic stress disorder. Cannabidiol does so by reducing fear expression acutely, and by disrupting fear memory reconsolidation and enhancing fear extinction, both of which can result in the lasting reduction of learned fear. Recent studies have also begun to determine the effects of cannabidiol on drug memory expression using paradigms with translational relevance to addiction. Emerging evidence suggests that cannabidiol reduces the expression of drug memories acutely and by disrupting their reconsolidation. Here we review the literature demonstrating the anxiolytic effects of cannabidiol before focusing on studies investigating its effects on various fear and drug memory processes. Understanding how cannabidiol regulates emotion and emotional memory processing may eventually lead to its use in treating anxiety-related and substance abuse disorders.

**Abbreviations**

- 5-HT<sub>1A</sub>: serotonin<sub>1A</sub>
- AFC: auditory fear conditioning
- BNST: bed nucleus of the stria terminalis
- BZD: benzodiazepine
- CB<sub>1</sub>: cannabinoid type 1
- CB<sub>2</sub>: cannabinoid type 2
- CBD: cannabidiol
- CFC: contextual fear conditioning
- CS: conditioned stimulus
- CUS: chronic unpredictable stress
- dIPAG: dorsolateral periaqueductal gray
- EPM: elevated plus-maze
- ETM: elevated T-maze
- FAAH: fatty acid amide hydrolase
- FAPBs: fatty acid-binding proteins
- fMRI: functional magnetic resonance imaging
- ICR: Institute of Cancer Research
- i.c.v.: intracerebroventricular
- IL: infralimbic
- i.p.: intraperitoneal
- LDT: light-dark test
- MBT: marble burying test
- OFC: olfactory fear conditioning
- NSF: novelty suppressed feeding
- PAG: periaqueductal grey
- PL: prelimbic
- PPARγ: peroxisome proliferator-activated receptor gamma
- PTSD: post-traumatic stress disorder
- SCR: skin conductance response
- SHR: spontaneously hypertensive rat
- SPECT: single-photon emission computed tomography
- THC: delta-9-tetrahydrocannabinol
- TRP: transient receptor potential
- TRPV<sub>1</sub>: transient receptor potential vanilloid1
- US: unconditioned stimulus
Introduction

Anxiety (e.g. generalized and social anxiety, panic, phobias), trauma-related (i.e. post-traumatic stress disorder (PTSD)), and substance abuse disorders are serious forms of mental illness associated with a significant lifetime prevalence. These disorders pose an enormous social and financial burden as they are often chronic in nature and inadequately treated (Di Luca et al., 2011). Certain anxiety-related disorders (i.e. phobias, PTSD) and addiction are characterized by aberrant and persistent emotional memories of fear- and drug-related stimuli. These discrete or contextual cues can trigger the emergence of symptoms or even their re-emergence after treatment, highlighting the limited effectiveness of currently available psychological and pharmacological therapies to curtail symptom relapse over the long-term (Tronson and Taylor, 2013; Everitt, 2014; Kindt, 2014; Singewald et al., 2015). Moreover, there is also significant co-morbidity between substance abuse disorders and PTSD, which can further complicate how PTSD develops and is treated. For example, the learning and memory processes involved in the psychological therapies that are used for treating PTSD can be adversely affected by different abused drugs, which may also have complex drug-drug interactions with pharmacological treatments for PTSD (Tipps et al., 2014). Thus there is an urgent need to improve the treatment of these disorders.

An area of real promise in this field concerns the use of existing or novel medications as adjuncts to psychological therapies to enhance the efficacy of treatment. Cannabidiol (CBD) is one such drug that shows therapeutic potential in a broad range of neurological and psychiatric diseases (Campos et al., 2012b). This phytocannabinoid is the main non-psychotomimetic constituent of the Cannabis sativa plant and mounting evidence indicates that CBD has anxiolytic properties (Blessing et al., 2015). Emerging preclinical and clinical evidence also indicates that CBD regulates different aversive and appetitive memory processes (Prud’homme et al., 2015; Jurkus et al., 2016), in keeping with the findings of recent studies showing a role for CBD in modulating other types of memory, such as novel object and social recognition, in cognitively impaired animals (Fagherazzi et al., 2012; Cheng et al., 2014). In this paper we begin with a brief historical account of the discovery of CBD and touch on the first studies that investigated its behavioural effects in rodents and humans. We then review the literature on CBD regulation of anxiety and the pharmacological and brain mechanisms involved. The bulk of the paper focuses on discussing the findings from the growing number of mostly preclinical studies that have examined the regulation of
learned fear and, more recently, addictive drug memory processing by CBD. Importantly, these studies have used experimental procedures with clinical relevance for understanding the psychological and neurobiological mechanisms involved in the pathophysiology and treatment of anxiety-related and substance abuse disorders.

**CBD discovery and initial studies on its behavioural effects**

The *Cannabis sativa* plant contains more than 100 chemically related terpenephenol components called phytocannabinoids (Izzo et al., 2009; Gold, 2015). Since the seminal work of Raphael Mechoulam’s group in the 1960s, Delta-9-tetrahydrocannabinol (THC) is considered the main component responsible for the pharmacological effects of the plant (Gaoni and Mechoulam, 1964). The second major component of most samples of *Cannabis sativa* is CBD. Originally isolated by Adams and co-workers in 1940 (Adams et al., 1940), its structure was elucidated by Mechoulam and Shvo in 1963. Although the CBD molecule is similar to THC, it has a distinct spatial conformation that could help to explain their different pharmacological properties. Whereas THC has a planar conformation, CBD presents a “bent” structure with two rings at a right angle to each other (Burstein, 2015).

Initial studies performed in the 1970s, mostly in Brazil, indicated that CBD could block some effects induced by THC in rodents (Karniol and Carlini, 1973; Russo and Guy, 2006). Following these initial studies, Zuardi and collaborators investigated if CBD could prevent the effects of high doses of THC in healthy human volunteers. They found that it attenuates the psychotomimetic and anxiogenic effects of THC (Zuardi et al., 1982). Although the mechanisms of action of these two drugs were completely unknown at that time, the fact that not all effects of THC were blocked by CBD indicated that the latter was not simply an antagonist of a putative THC receptor. On the contrary, the study suggested that CBD possesses its own antipsychotic and anxiolytic properties (Zuardi et al., 1982).

**Laboratory animal tests used to assess the anxiolytic properties of CBD**

The potential anxiolytic effect of CBD was initially investigated in preclinical studies. Several animal tests have been employed to explore the effects of putative anxiolytic drugs and the neurobiology of anxiety, which can be defined separately to fear as the emotional response to potential or anticipated (as opposed to actual and present) threat (Tovote et al., 2015). These tests are based on the measurement of defensive behaviours (either active or inhibitory) expressed in response to a threatening or unpleasant stimulus (Campos et al., 2013a). The initial preclinical studies investigating the possible anxiolytic-like effects of
CBD were performed in learning-based models and produced mixed results. These apparently conflicting results were later explained by Guimaraes et al. (1990) using the elevated plus-maze (EPM). This is a commonly used test to investigate anxiety-like behaviour in preclinical studies and is based on the natural aversion that rodents show to open spaces (Handley and Mithani, 1984; Pellow et al., 1985; Treit et al., 1993; Carobrez and Bertoglio, 2005).

Using the EPM, and performing a full dose-response curve in rats, Guimaraes and co-workers showed that acute systemic administration of CBD produces a typical ‘bell-shaped’ dose-response curve, being anxiolytic at low and intermediate doses but not at high doses. Although some contradictory results exist in the literature, most studies using unlearned or operant conditioning models of anxiety have confirmed these initial findings and the studies investigating CBD effects in classical (Pavlovian) conditioning models also go in the same direction, which will be discussed separately below (summarized in Tables 1-2). Moreover, these anxiolytic effects of CBD in animals have been replicated in human studies using healthy subjects exposed to anxiety-provoking stimuli or situations (Zuardi et al., 1982, 1993; Crippa et al., 2004; Fusar-Poli et al., 2009, 2010) and in patients with anxiety, and possibly also substance abuse, disorders (Bergamaschi et al., 2011, Crippa et al., 2011; Hurd et al., 2015; Shannon and Opila-Lehman, 2016; summarized in Table 3).

**Pharmacological mechanisms and brain sites involved in the anxiolytic effects of CBD**

The potential therapeutic effects of CBD have been related to multiple pharmacological mechanisms, including the agonism of serotonin 5-HT_{1A} receptors, inhibition of re-uptake and/or metabolism of the endocannabinoid anandamide (resulting indirectly in cannabinoid receptor activation), activation of transient receptor potential vanilloid 1 (TRPV1) channels, inhibition of adenosine re-uptake, antagonism of GPR55, agonism of PPAR\(\gamma\) receptors, intracellular Ca\(^{2+}\) increase, and anti-oxidative effects, among others (summarized in Fig 1; the pharmacological nomenclature used throughout conforms with The Concise Guide to PHARMACOLOGY (Alexander et al., 2013)). These pharmacological mechanisms have been discussed recently in several reviews (Izzo et al., 2009; Campos et al., 2012a; Ibeas Bih, et al., 2015; McPartland et al., 2015), to which the reader is referred. So far, however, only two of these mechanisms - 5-HT_{1A} receptor activation and indirect potentiation of endocannabinoid transmission - have been implicated in the attenuation of defensive responses to threatening or stressful stimuli.
Two primary brain systems organize defensive responses to threatening stimuli: one responsive to innate threats and the other responsible for the association between neutral and aversive stimuli, although the neural circuit mechanisms underlying the regulation of anxiety and learned fear show considerable overlap (for reviews see McNaughton and Corr, 2004; Canteras et al., 2010; Gross & Canteras, 2012; Tovote et al., 2015). The brain areas implicated in the anxiolytic effects of cannabidiol include certain medial prefrontal cortical subregions (e.g. prelimbic (PL) and infralimbic (IL) cortex), the bed nucleus of the stria terminalis (BNST), periaqueductal grey (PAG), and amygdala. This evidence comes from preclinical studies and functional imaging studies in humans, which have confirmed the involvement of some of these brain areas. For example, CBD reduced amygdala activation in both mice and humans (Todd and Arnold, 2016; Crippa et al., 2004). Activity in and functional connectivity between the amygdala and anterior cingulate cortex, the homologous region to the rodent dorsomedial prefrontal cortex, were both also decreased by CBD when viewing fearful facial expressions (Fusar-Poli et al., 2009, 2010).

In an initial preclinical study using the EPM test, Campos and Guimarães (2008) showed that the anxiolytic-like effects of CBD injected into the dorsolateral PAG (dlPAG) were prevented by local treatment with the 5-HT1A receptor antagonist WAY100635. Even if this drug can also activate D4 receptors (Chemel et al., 2006), the anti-aversive effects of CBD were similar to other 5-HT1A receptor agonists infused into the dlPAG (Graeff, 2002). 5-HT1A receptor involvement in the acute anxiolytic/anti-stress effect of CBD was further demonstrated in other relevant brain regions, including the BNST (Gomes et al., 2011) and IL cortex (Marinho et al., 2015). Moreover, systemic treatment with 5-HT1A receptor antagonists was also able to prevent this CBD-induced anxiolysis (see Table 1).

In the marble-burying test and after repeated administration, however, CBD effects on anxiety seem to depend on cannabinoid type 1 (CB1) receptors rather than 5-HT1A receptors (Casarotto et al., 2010; Campos et al., 2013; Nardo et al., 2014). Even if the (+)-CBD enantiomer shows affinity for CB1 receptors, the naturally occurring (-)-CBD does not bind to these receptors (Hanus et al., 2005), indicating that the CB1 receptor-mediated anti-aversive effects of CBD are probably indirect. Bisogno et al. (2001) showed that CBD blocked the reuptake and metabolism of anandamide \textit{in vitro}. In the same direction, using embryonic hippocampal cells, Campos et al. (2013b) showed that the increase in cell proliferation induced by CBD is prevented by antagonism of either CB1 or cannabinoid type 2 (CB2) receptors, as well as by overexpression of fatty acid amide hydrolase (FAAH), the enzyme responsible for anandamide metabolism. More recently, Dale Deutsch's group demonstrated
that CBD binds to fatty acid binding proteins necessary for the transport of anandamide from the plasma membrane to intracellular FAAH, which might be a primary mechanism by which CBD decreases anandamide uptake/metabolism (Elmes et al., 2015). Consistent with these in vitro studies, the anti-stress (in mice) and antipsychotic (in humans) effects of repeated CBD administration were associated with increased hippocampal and serum levels, respectively, of anandamide (Campos et al., 2013b, Leweke et al., 2012).

**Emotional learning and memory processing**

We first summarize the psychological mechanisms involved in classical conditioning, a type of associative learning whereby discrete cues or contexts come to predict the occurrence of threatening or rewarding stimuli, before reviewing the evidence demonstrating a role for CBD in regulating different fear and drug memory processes. During conditioning an innocuous conditioned stimulus (CS), which can be a discrete cue (e.g. sound, light, odor) or a context (e.g. testing chamber/arena), becomes associated with an aversive (e.g. footshock) or appetitive (e.g. drug reward availability) unconditioned stimulus (US). After conditioning, the CS-US association undergoes consolidation into long-term memory and later presentation of or re-exposure to the CS alone initially elicits conditioned fear (e.g. freezing, avoidance) or drug-seeking (e.g. lever pressing, place preference) responses (Peters et al., 2009). Retrieval of the CS can make emotional memories labile by destabilizing the memory trace, which allows for these memories to be maintained or updated through the process of reconsolidation (Lee, 2009). Repeated presentations of or prolonged exposure to the CS causes the extinction of emotional memories, resulting in the formation of a new CS-no US association which competes with the original emotional memory to suppress conditioned responding to the CS (Peters et al., 2009). Understanding how behavioural and/or pharmacological interventions can attenuate conditioned responding, disrupt memory reconsolidation, and/or enhance extinction has clinical relevance given that all of these mechanisms are potential therapeutic strategies for alleviating the symptoms of PTSD (i.e. pathological fear) and addiction (i.e. drug craving) (Tronson and Taylor, 2013; Everitt, 2014; Kindt, 2014; Singewald et al., 2015).
CBD effects on fear memory processing

As alluded to above, growing evidence indicates that CBD also regulates learned fear (see Table 2). Systemic CBD administration has been shown to reduce the expression of fear memory when given acutely (Zuardi and Karniol, 1983; Resstel et al., 2006; Lemos et al., 2010; Jurkus et al., 2016). CBD has also been reported to impair the acquisition of fear learning, given that acute systemic administration before fear conditioning resulted in attenuated fear expression during later memory retrieval testing (Levin et al., 2012). Fear memory consolidation is equally impaired by acute systemic administration of CBD when given after conditioning (Stern et al., 2016). In contrast, the reported effects of repeated CBD administration on fear memory expression are still scarce and conflicting. In one study, daily injections for 14 days prior to conditioning enhanced fear expression during retrieval testing, suggesting that chronic CBD facilitated fear learning (ElBatsh et al., 2012), whereas another study showed no effect of CBD on fear conditioning when administered for 21 days (Cheng et al., 2014).

Studies indicate that CBD also modulates the extinction and reconsolidation of conditioned fear, leading to lasting effects on learned fear expression. Intracerebroventricular infusions of CBD given before three extinction sessions resulted in enhanced contextual fear extinction (Bitencourt et al., 2008). Systemic administration of CBD given acutely before extinction has been shown to affect contextual fear extinction depending on the strength of fear conditioning beforehand. CBD impaired extinction after weak conditioning but enhanced extinction after strong conditioning (Song et al., 2016). However, CBD given systemically before auditory fear extinction reduced fear expression acutely without affecting extinction memory (Jurkus et al., 2016). Interestingly, a study in humans also showed that CBD had no effect on the extinction of visual fear memory when given before extinction but it did enhance extinction memory when given immediately after extinction (Das et al., 2013).

Contrary to the reported facilitatory effects of CBD on fear extinction, this drug has been shown to disrupt the reconsolidation of contextual fear memory after its brief retrieval (Stern et al., 2012; Gazarini et al., 2015; Stern et al., 2015), although these contrasting effects of CBD on fear extinction and memory reconsolidation both result in the lasting reduction of learned fear expression. The disruptive effect of systemic CBD administration on reconsolidation required that it was given immediately after memory retrieval as CBD had no effect if it was given without, or six hours after, retrieval. CBD was also able to disrupt the reconsolidation of both newer and older fear memories. Moreover, the subsequent reduction of learned fear expression lasted for over 21 days and was not reinstated by later shock.
presentation, indicating that the effects of CBD were due to disrupted memory reconsolidation and not enhanced extinction (Stern et al., 2012).

In another study, CBD given immediately after retrieval disrupted the reconsolidation of an abnormally persistent fear memory when the partial NMDA receptor agonist D-cycloserine was first administered before retrieval to facilitate memory destabilization. Fear memory was strengthened pharmacologically by enhancing adrenergic transmission immediately after conditioning, resulting in generalized fear expression and impaired fear suppression by extinction (Gazarini et al., 2015). Understanding the mechanisms underlying reconsolidation disruption of such fear memories is important because evidence indicates that strong fear memories can show resistance to pharmacological disruption of reconsolidation (Lee, 2009), which has implications for using this potential therapeutic approach to weaken traumatic memories in the treatment of PTSD.

**Pharmacological mechanisms and brain sites involved in the effects of CBD on learned fear**

Just as the anxiolytic effects of CBD involve a direct effect on 5-HT₁A receptors and an indirect effect on cannabinoid receptors via elevated endocannabinoid levels, so too do its effects on different fear memory processes. Similarly, there is overlap in the neural circuitry involved in mediating the effects of CBD on anxiety and learned fear. The reduction in conditioned fear expression induced by CBD was accompanied by attenuated c-Fos expression in the PL and IL cortices and the BSNT. Moreover, CBD infusion into the BNST or PL cortex reduced fear memory expression, although infusing CBD into the IL cortex enhanced the expression of learned fear (Lemos et al., 2010). This discrepancy between the effects of CBD infused into the PL or IL cortex is likely due to these medial prefrontal cortical subregions exerting opposing influences on learned fear, with the former facilitating its expression and the latter being involved in its suppression and/or extinction (Fenton et al., 2014; Giustino and Maren, 2015). The regulation of conditioned fear expression by CBD in these brain areas was shown to be 5-HT₁A receptor-dependent (Gomes et al., 2012; Fogaça et al., 2014; Marinho et al., 2015). The inhibitory effect of CBD on the acquisition of fear conditioning has also been shown to depend on 5-HT₁A receptor activation in the nucleus accumbens shell (Norris et al., 2016).
In contrast to the acquisition and expression of fear memory, the consolidation, reconsolidation, and extinction of learned fear involves (indirect) cannabinoid receptor activation. The inhibitory effect of CBD on fear memory consolidation was blocked by CB₁ or CB₂ receptor antagonist pretreatment (Stern et al., 2016). The facilitatory effect of intracerebroventricular CBD infusion on fear extinction was inhibited by prior CB₁ receptor antagonism but not TRPV1 channel blockade (Bitencourt et al., 2008). CBD was shown to act in the IL cortex to facilitate fear extinction as infusing CBD into this region enhanced extinction, an effect which also depended on CB₁ receptors (Do Monte et al., 2013). The disruptive effect of CBD on fear memory reconsolidation was blocked by pretreatment with a CB₁ receptor antagonist given systemically or infused into the PL cortex, whereas prior 5-HT₁A receptor antagonism had no effect on the disruption of reconsolidation by CBD (Stern et al., 2012, 2014).

**CBD effects on addictive drug memory processing**

In contrast to the study of fear memories, to date there has been a much more limited exploration of the effects of CBD on addictive drug-related memories. This necessitates a narrative review of the relevant literature, which follows below. Moreover, the small number of studies has been conducted across a variety of experimental paradigms and with different drugs of abuse. These drugs can elicit sensitized responses with intermittent repeated administration, which is context-dependent and thereby reliant upon context-drug associations. Similarly, the acquisition and expression of conditioned place preference behaviour depends upon the integrity of context-drug and/or cue-drug associations. Finally, cue-drug associations can precipitate cue-induced relapse of drug seeking in rodents previously trained to self-administer drug (Aguilar et al., 2009; Steketee and Kalivas, 2011). Each of these paradigms can be studied using stimulants (e.g. cocaine, amphetamine), opiates (e.g. heroin, morphine), and other drugs (e.g. alcohol, nicotine, etc.).

Unlike THC, studies have shown that CBD lacks any rewarding effects of its own given that it fails to induce conditioned place preference or enhance the reinforcing effects of electrical brain self-stimulation (Parker et al., 2004; Vann et al., 2008; Katisdoni et al., 2013). In a study of amphetamine-induced locomotor sensitization, infusions of CBD (100 ng) into the shell subregion of the nucleus accumbens attenuated the development of locomotor sensitization (Renard et al., 2016). While this might suggest that CBD impaired the formation of an amphetamine memory that supports locomotor sensitization, these findings were within the context of mesolimbic mechanisms involved in the potential antipsychotic action of CBD.
Moreover, even though the attenuation of locomotor sensitization was paralleled by modulation of cellular mechanisms of synaptic plasticity, it remains a challenge to disambiguate learning-related behavioural effects from modulation of drug reward (c.f. Katsidoni et al., 2013; Prud'homme et al., 2015), which would impact upon reward-dependent learning. The non-mnemonic interpretation is supported by a failure of CBD to prevent the acquisition of amphetamine place preference (Parker et al., 2004). However, while it appears that CBD does not disrupt the formation of amphetamine-related memories, this does not rule out potential effects on memories formed in relation to other drugs of abuse.

Subsequent to their acquisition, CBD might affect the expression of drug memories. Here there appears to be a contrast depending upon the drug reward under study. Acute administration of CBD (5 and 10 mg kg\(^{-1}\)) did not alter cocaine self-administration or cue-induced relapse to cocaine seeking (Mahmud et al., 2016), and so failed to replicate an earlier study of heroin self-administration (Ren et al., 2009). While CBD (5 and 20 mg kg\(^{-1}\)) similarly did not alter heroin self-administration, there were effects on cue-induced relapse to heroin seeking (Ren et al., 2009), a measure of cue-heroin memory expression. CBD (5 mg kg\(^{-1}\)) reduced responding at a cue-induced relapse test, but only when given 24 hr, and not 30 min, prior to the test. This long-lasting impact upon the expression of the cue-heroin memory was even more persistent (up to 14 days) when three consecutive daily injections of 5 mg kg\(^{-1}\) CBD were given. This ability of CBD to have such long-lasting effects may be mediated by an upregulation of AMPA GluR1 receptors in the nucleus accumbens (Ren et al., 2009).

The impaired expression of cue-heroin relapse in response to CBD administration in animals suggests that this drug might have anti-relapse properties in opiate addiction in humans. This has been explored in a preliminary study of heroin addicts, in which participants were given daily doses of CBD (400 or 800 mg) or placebo for 3 days (Hurd et al., 2015). CBD reduced craving both 24 hr and 7 days later, mirroring the preclinical rodent study (Ren et al., 2009). This beneficial effect of CBD may not be limited to opiate addiction as a conceptually similar, albeit more modest, effect was also previously observed in tobacco smokers (Morgan et al., 2013). In this small week-long study, smokers were instructed to inhale a metered dose of CBD (400 µg) or placebo when they felt like smoking. CBD acutely reduced the number of cigarettes smoked but this effect was not maintained after the cessation of CBD administration. Interestingly, and in contrast to the heroin study, CBD did not alter craving, either acutely or persistently. Therefore, it is not clear whether CBD has generalised effects on the expression of cue-drug memory to elicit craving and precipitate relapse, or whether its effects are specific to certain classes of addictive drugs.
For the maintenance (i.e. reconsolidation) of drug-related memories, there is a single study on morphine and cocaine conditioned place preference. When the place preference memory was briefly reactivated in order to trigger reconsolidation, CBD administration (10 mg kg\(^{-1}\)) immediately thereafter led to an impairment in the subsequent maintenance of both cocaine and morphine memories to reduce place preference at test (de Carvalho and Takahashi, 2016). This was a long-lasting effect, which is usually evidence for reconsolidation impairments. However, the study lacked a true non-reactivation control, and so the long-lasting impairment, especially for morphine place preference, is not dissimilar to the aforementioned persistent reduction in the expression of cue-heroin memories in the self-administration setting (Ren et al., 2009). Therefore, it remains unclear whether CBD indeed impairs the reconsolidation of drug memories. Nevertheless, there are indications from the comparison between the place preference and self-administration studies to suggest that their results might be underpinned by qualitatively different processes. For example, while the CBD-induced impairment failed to ameliorate heroin-primed reinstatement of drug seeking (Ren et al., 2009), post-reactivation CBD did prevent morphine-primed reinstatement of place preference (de Carvalho and Takahashi, 2016). Moreover, the contrasting effects of post-reactivation CBD and acute CBD treatment on the subsequent expression of cocaine memories (de Carvalho and Takahashi, 2016) suggests that the impairment in cocaine place preference is not simply explained by long-lasting modulation of drug memory expression.

Similarly, there is a single study of CBD and drug memory extinction. Injection of CBD (5 mg kg\(^{-1}\)) prior to an extinction trial enhanced the subsequent reduction in cocaine and amphetamine place preference (Parker et al., 2004). Despite the lack of a no-extinction control, the observation that CBD reduces the expression of stimulant-induced place preference again suggests that such a reduction was, at least in part, due to the concomitant extinction trial. Interestingly, the effect of CBD to reduce cocaine and amphetamine place preference in this extinction study (Parker et al., 2004) is rather similar to the previous observation that CBD impairs the reconsolidation of morphine and cocaine memories in the same place preference setting (de Carvalho and Takahashi, 2016). Indeed, while there was a difference in the timing of CBD administration between the two studies, the single behavioural trial that served to extinguish (Parker et al., 2004) or destabilise (de Carvalho and Takahashi, 2016) the drug memory did not differ greatly. The extinction trial was 15 min in duration, compared to a 10 min reactivation trial, although the former was a confinement to the drug-paired chamber, whereas the latter was a test. Moreover, the conditioning parameters were rather similar across the two studies, and also in prior studies of
reconsolidation that have used 30-min confined reactivation trials for amphetamine place preference (Sakurai et al., 2007), 20-min confined reactivation trials for cocaine place preference (Valjent et al., 2006) and 10-min confined reactivation trials for morphine and nicotine place preference (Wang et al., 2008; Fang et al., 2011). Given also that the parameters of appetitive memory reconsolidation and extinction are usually well distinguished, such that they are each typically defined by much different durations of context re-exposure or numbers of cue presentations (Flavell and Lee, 2013), it is unclear if CBD both enhances extinction and impairs reconsolidation of drug memories. It is perhaps more likely that the two observed effects of CBD to reduce later drug place preference (Parker et al., 2004; de Carvalho and Takahashi, 2016) instead reflect qualitatively similar processes. Appealing simply to the parametric comparisons presented above, we would conclude that there is stronger evidence for CBD impairing drug memory reconsolidation than there is for it enhancing drug memory extinction. Furthermore, given that pharmacological enhancement of extinction is usually dependent upon appreciable extinction-mediated memory reduction (Webber et al., 2007; Bouton et al., 2008), and there was no evidence for any such reduction in the CBD study (Parker et al., 2004), it remains unclear if CBD actually enhances drug memory extinction.

Concluding remarks and future directions

Converging lines of evidence have established that acute CBD treatment is anxiolytic in both animals and humans. A growing number of preclinical studies also indicate that this drug reduces fear memory expression when given acutely. Importantly, CBD results in an enduring reduction in learned fear expression when given in conjunction with fear memory reconsolidation or extinction by disrupting the former and facilitating the latter. This makes CBD a potential candidate for testing as a pharmacological adjunct to psychological therapies or behavioural interventions used in treating PTSD and phobias. These effects of CBD are mediated at least in part by 5-HT1A receptors and indirectly via endocannabinoid-mediated action on cannabinoid receptors, although the involvement of other possible pharmacological mechanisms has not yet been investigated. Studies have begun to elucidate the neural circuit mechanisms underlying the effects of CBD on anxiety and learned fear. The recent functional imaging studies in humans that have examined the alterations in brain activity that accompany the anxiolytic effects of CBD may inform future preclinical and clinical studies investigating the wider neural circuitry involved in mediating its effects on learned fear. In contrast to anxiety and learned fear, research on CBD regulation of addictive drug memory...
processing is still in its infancy. Further studies are therefore needed to determine the psychological, pharmacological and brain mechanisms involved in the attenuation of drug memory expression by CBD in relation to different classes of abused drugs. Given the significant co-morbidity between anxiety-related and substance abuse disorders, CBD could also be investigated as a common treatment for such disorders. An outstanding issue is to determine the effects of chronic CBD treatment on different emotional memory processes. For example, one potential therapeutic strategy is to use CBD chronically to reduce symptoms by dampening fear and/or drug memory expression. However, CBD given acutely during the psychological therapy session to impair memory reconsolidation or enhance extinction might be sufficient for facilitating such treatment. Another important consideration is how CBD would be delivered in the treatment of these disorders. Most of the recreationally used cannabis available today contains low levels of CBD and high levels of THC, which can exacerbate symptoms, although cannabis strains containing a more favourable CBD:THC ratio might be an option (Hurd et al., 2015). Similarly, novel formulations of CBD containing only trace amounts of other phytocannabinoids have recently become available for the putative treatment of childhood epileptic disorders (e.g. Epidiolex, GW Pharmaceuticals; Gofshteyn et al., 2016). In summary, this line of research may lead to the potential development of CBD for use in treating anxiety-related and substance abuse disorders in the future.

Acknowledgements

FSG, JLCL, and CWS were funded jointly by a FAPESP-University of Birmingham-University of Nottingham pump-priming award (2012/50896-8). LJB was funded by a Brazilian CNPq research fellowship (307895/2013-0). The funders had no other involvement in any aspect of this work. FSG is co-inventor of the patent “Fluorinated CBD compounds, compositions and uses thereof. Pub. No.: WO/2014/108899. International Application No.: PCT/IL2014/050023”; Def. US no. Reg. 62193296; 29/07/2015; INPI in 19/08/2015 (BR1120150164927). The authors have no other potential conflicts of interest to declare.

Fig 1. The main molecular targets and potential mechanisms of action of CBD. This drug inhibits both fatty acid amide hydrolase (FAAH), the enzyme which metabolizes anandamide, and fatty acid-binding proteins (FAPBs), which mediate the transport of anandamide to FAAH; both mechanisms ultimately result in the indirect activation of cannabinoid type 1 (CB₁) and/or type 2 (CB₂) receptors. CBD also activates the serotonin₁A (5-HT₁A) receptor, peroxisome proliferator-activated receptor gamma (PPARγ), and the transient receptor potential (TRP) channels TRPV₁, TRPA₁, and TRPV₂. Finally, CBD inhibits adenosine reuptake and antagonizes GPR55, TRPM₈ and T-type Ca²⁺ channels. 5-HT₁A and (indirect) cannabinoid receptor activation are the mechanisms that have been implicated in the anxiolytic effects of CBD to date (see Ibeas Bih et al. (2015) and McPartland et al. (2015) for further details).
