THE IMPACT OF MATERNAL NUTRIENT INTAKE ON THE HUMAN FETUS

Food intake and appetite are driven primarily by the need to ensure sufficient protein intake (the reference range for ‘normal’ human protein consumption is 80–120 g/day or 15–20% of total calories 1.500–2,500 kcal/day). Dietary protein dilution through consumption of nutrient-poor, energy-rich food engenders increased energy intake. Although undernutrition has historically been of greater concern to developing or low-income nations, a recent study showed that even in countries with a high gross domestic product rating, 38% of pregnant women were not reaching the 16% recommended protein intake. Indeed, rather surprisingly, the World Health Organization (WHO) estimates that there were 1.1 million children ≤2 standard deviations weight-for-height (an index of protein energy malnutrition (PEM)) in the USA. Insufficient supply of vital nutrients, such as amino acids and metabolites generated by amino acid oxidation, during the reproductive years, can have a plethora of direct effects on the mother and her developing fetus and indirectly affect the subsequent individual as they grow toward adulthood.

JUSTIFICATION AND LIMITATIONS OF ANIMAL MODELS

Ever since Barker first proposed that adult disease, especially heart disease, could be linked to low birthweight via fetal nutrition,8 a number of clinical and many laboratory animal studies16 have been carried out to confirm the biological validity of the hypothesis. Animal models are widely used and offer potential mechanistic insights through control of environmental and genetic variation, whilst manipulating individual nutrients, such as protein, through pregnancy and/or lactation, together with the ease of longer-term follow-up (a rat reaches middle age 18 months of age). Animal models therefore allow for adult interventions to be tested to assess potential elements of the programmed phenotype, including multi-generational transmission over a reasonable timescale: a response not possible in clinical cohorts. As a case-in-point, 12 generations of protein malnutrition in rats (i.e. 6.8% protein as a percentage of total calories when protein adequacy in pregnant rats is considered to be 12–18% protein intake) had diverse effects on offspring, including lower birth weight, body size, and fertility; the effects reversed within three generations of nutritional rehabilitation.11 Each laboratory or farm animal used to ‘model’ a given experimental intervention with potential resonance for human cohorts needs to define why that animal is appropriate whilst accepting the potential limitations. These issues are too broad for a full discussion here, but readers should consider the following reviews.12,13

THE IMPACT OF MATERNAL MALNUTRITION ON THE ANIMAL FETUS

The first animal studies to model maternal protein-energy malnutrition in the lab showed that even with moderate protein restriction we were able to observe some developmental programming effects carried via the sperm that affect post-fertilisation development. Mechanisms underpinning such effects have been of greater concern to developing or low-income nations, a recent study showed that even in countries with a high gross domestic product rating, 38% of pregnant women were not reaching the 16% recommended protein intake. Indeed, rather surprisingly, the World Health Organization (WHO) estimates that there were 1.1 million children ≤2 standard deviations weight-for-height (an index of protein energy malnutrition (PEM)) in the USA. Insufficient supply of vital nutrients, such as amino acids and metabolites generated by amino acid oxidation, during the reproductive years, can have a plethora of direct effects on the mother and her developing fetus and indirectly affect the subsequent individual as they grow toward adulthood.

ABSTRACT

It is well known that consumption of a balanced diet throughout adulthood is key toward maintenance of optimal body weight and cardiovascular health. Research using animal models can provide insights into the programming of short and long-term health by parental diet and potential mechanisms by which, for example, protein intake may influence fetal development, adolescent health, and adult morbidity/mortality. Malnutrition, whether consumption of too many or too few individual nutrients or energy, is detrimental to health. For example, in Westernised societies, one of the principal factors contributing towards the global epidemic of obesity is over-consumption of calories, relative to the expenditure of calories through physical activity. A large body of evidence now suggests that many chronic diseases of adulthood, such as obesity and diabetes, are linked to the nutritional environment experienced by the fetus in utero. Maternal consumption of a poor-quality, nutritionally unbalanced diet can programme offspring to become obese, develop high blood pressure and diabetes, and to experience premature morbidity and mortality. More recently, paternal diet has also been shown to influence offspring health through effects carried via the sperm that affect post-fertilisation development. Mechanisms underpinning such developmental programming effects remain elusive, although there is emerging development of the microvasculature in the heart and pancreas, particularly after exposure of the mother (or father) to a protein restricted diet, has been proposed as one mechanism linking early diet to perturbed adult function. In this brief review, we explore the longer-term consequences of maternal and paternal protein intakes on the progeny. Using evidence from relevant animal models, we illustrate how protein malnutrition may ‘programme’ lifelong health and disease outcomes, especially in relation to pancreatic function and insulin resistance, and cardiac abnormalities.

Keywords: Protein restriction, accelerated growth, cardiac, insulin, pancreas.
A number of studies have been conducted into the effects of maternal protein restriction on the fetus in relation to metabolism, insulin resistance, and obesity. Fernandez-Twinn et al. discovered that maternal protein restriction (rats: 8 and 20% protein; gestation and lactation) led to hyperinsulinaemia and reduced muscle insulin action i.e. peripheral insulin resistance in the 21-month old offspring. In protein restricted exposed mice where accelerated postnatal catch-up growth was not observed (8% versus 20% casein, conception to weaning), no differences in adult glucose tolerance were noted relative to protein replete controls. These effects of protein dilution persist into adulthood. They illustrate that the environmental burden on offspring phenotype is not just the territory of the mother. The implication for future generations is clear: malnutrition during early development can exert its deleterious effects for many generations to come, even after correction of the nutritional inadequacy. The likely mechanism is epigenetic inheritance. Jean-Baptiste Lamarck would be proud.

**PROGRAMMING OF OFFSPRING CARDIAC FUNCTION**

Cardiac dysfunction has been observed in rats subjected to maternal protein malnutrition (9% versus 18% casein prior to mating, throughout pregnancy) and in aged male and female adults (40 weeks of age) that had left ventricular hypertrophy and increased pulse pressure. Hypertension has also been observed in 7 week old offspring (rat: 9% versus 18% casein prior to mating, throughout pregnancy) and although the maternal protein restricted offspring were born smaller, pup weights were unaltered in comparison to controls at 7 weeks of age. Elevated systolic blood pressure after maternal protein restriction appears to be a relatively consistent outcome regardless of the period of nutritional restrictions even when protein malnutrition is confined to the period prior to mating or very early during gestation; although others have noted reduced systolic arterial pressure with elevated sympathetic tone in rats 90 days postpartum (8% versus 17% casein; gestation and lactation). Tappa et al. also observed maternal protein restriction to have expressed ejection fractions in the first 4 weeks of life, increased left ventricular internal diameter and posterior cardiac wall thickness during both diastolic and systolic phases of the cardiac cycle to 8 weeks of age, together with a multitude of changes to cardiac gene expression. Recently, maternal protein restricted (8% versus 20% throughout gestation; rat) induced accelerated postnatal growth to 22 days postnatal age that was accompanied by increased cardiac nitrosative and oxidative-stress with concomitant increases in DNA damage and base-excision repair enzyme expression. Indeed, greater effects on the heart appear to be observed when maternal protein restriction is followed by accelerated post-natal growth during adolescence. Furthermore, it is increasingly becoming apparent that protein-malnutrition induced programming of cardiovascular function is highly sex-specific with males, in general, being more susceptible than females. Exact mechanisms have not been elucidated, although age-related changes in sex-hormone status and cellular action, coupled with programmed alterations to hypothalamic-pituitary-adrenal axis sensitivity are central to the effect.

**CONCLUSIONS**

Maternal or paternal consumption of a protein-restricted diet can have a range of physiologic outcomes in the offspring. In general, lower weight at birth is followed by accelerated post-natal growth. The latter has become designated as catch-up but may simply be regression to the mean. Nevertheless, accelerated early growth appears as powerful a programming stimulus as disproportionate fetal growth. The consequences for the ‘programmed’ individual have now extended beyond concern for the F1 generation to the F2 and F3 generations as epigenetic inheritance of an acquired phenotype becomes a reality. The fetal origins hypothesis matured into the developmental programming of adult health or disease, to encapsulate the multivariate effects on the fetus, the neonate and the growing adolescent individual. The paradigm has recently been extended to include paternal diet and in the years to come will no doubt be extended further to include grandmaternal and grandpaternal effects as the children of prospectively studied cohorts age and have families of their own. What is obvious is that the dire effects of early malnutrition will have an impact on populations for many generations to come.
