Abstract

The demand for high quality and specialty coffee is increasing worldwide. In order to meet these demands, a more uniform and standardized quality assessment of coffee is essential. The aim of this study was to make a sensory scientific and chemical characterization of common roasting defects in coffee, and to investigate their potential relevance for consumers' acceptance of coffee. To this end, six time-temperature roasting profiles based on a single origin *Arabica* bean were developed: one 'normal', representing a reference coffee free of defects, and five common roast defects ('dark', 'light', 'scorched', 'baked' and 'underdeveloped'. The coffee samples obtained from these beans were evaluated by means of 1) aroma analysis by Gas Chromatography-Mass Spectrometry (GC-MS), 2) sensory descriptive analysis (DA) by trained assessors, and 3) hedonic and sensory evaluation by consumers using a Check-All-That-Apply (CATA) questionnaire.

Multivariate analyses of aroma, DA, and CATA data produced similar sample spaces, showing a clear opposition of the light roast to the dark and scorched roasts), with the normal roast having average values of key aroma compounds. The DA data confirmed this indications and showed the normal roast to have a balanced sensory profile compared to the other defects. Importantly, the normal roast was also significantly preferred in the consumer

test (N = 83), and significantly associated to positive CATA attributes 'Harmonic', 'Pleasant', and 'Balanced'. Taken overall, the results provide a solid basis for understanding chemical and sensory markers associated with common roasting defects, which the coffee professionals may use internally in both quality control and product development applications.

Keywords: coffee, clean cup, food quality, roasting defects, consumers vs experts.

1 1. Introduction

² 1.1. Quality grading in the coffee industry vs. sensory analysis

With more than 2 billion cups consumed around the globe on an everyday 3 basis, coffee is the most important beverage commodity traded in world markets (Nair, 2010; Ponte, 2002). Coffee consumption rates have increased 5 1-2% per year worldwide during the last decades, and especially the demand 6 for specialty and high quality coffee has experienced the sharpest increase over the last years (Bhumiratana et al., 2011). Coffee quality is determined by numerous factors, such as the origin, post harvesting process and roasting 9 of the coffee beans, different grinding and brewing methods, and serving 10 conditions (Agresti et al., 2008; Baggenstoss et al., 2008; Brown and Diller, 11 2008; Lee and O'Mahony, 2002; Steen et al., 2017). In the coffee industry, 12 several quality grading methods are used to classify the coffee at different 13 stages of the production leading to a large number of classification systems 14 related to plant type, origin, process treatment, defect count or bean size 15 (Ribeiro et al., 2009). Such methods, however, do not necessarily relate much 16 to the eventual sensory quality of the brews. Therefore, sensory evaluation 17 is a crucial important tool to determine the drinking quality of the coffee. 18

In the coffee industry, sensory quality grading of brewed coffee, usually re-19 ferred to as 'cupping', is conducted by expert 'cuppers' (Feria-Morales, 2002; 20 Di Donfrancesco et al., 2014). Typically, the procedure consists of tasting 21 three to ten cups of the same coffee, prepared according to brewing condi-22 ²³ tions standardized with regard to temperature, contact time, water to coffee ratio, water quality and brewing method (SCAA, 2009; ISO, 2008). The 24 cupping score sheet includes important flavor attributes for coffee, ranging 25 from 0 to 10. In the current version, these are Fragrance/Aroma, Flavor, 26 Aftertaste, Acidity, Body, Balance, Uniformity, Clean Cup, Sweetness, De-27 fects, and Overall. However, unlike assessors in sensory descriptive analysis, 28

²⁹ cuppers do not rate the intensity but rather give a subjective appraisal of the ³⁰ individual attributes. For example, a high grade in Acidity would indicate ³¹ how well the sourness of the coffee fits within the context of that particular ³² coffee, regardless of absolute intensity. This blend of hedonic and analyti-³³ cal assessment marks perhaps the most important difference with scientific ³⁴ sensory analysis.

Generally speaking, expert cupping is more anchored in the product grad-35 ing tradition than it is in proper sensory analysis. Indeed, in spite of their 36 widespread application, from a scientific point of view current cupping pro-37 cedures can be criticized on several grounds. Firstly, while sensory science 38 methods rely of a larger pool of assessors to ensure robustness in the results, 30 the coffee branch mostly relies on few expert tasters with years of experience. 40 Oftentimes, only one or two tasters are responsible for the quality grading 41 of a large number of coffee samples, sometimes amounting to more than 200 42 cups per day. Furthermore, the tasting are often not blind, meaning that 43 the expert cuppers will typically have information about the coffee variety, 44 supplier, etc. (Feria-Morales, 2002). Finally, until recently¹ there was no 45 consensus regarding the sensory vocabulary or the use of particular scales, 46 which still vary quite substantially depending on the country of origin of the 47 coffee, and even on the individual company performing the cupping (Feria-48 Morales, 2002). Accordingly, two previous studies (Di Donfrancesco et al., 49 2014; Feria-Morales, 2002) have reported a poor correlations between results 50 from 'cupping' (sensory evaluation by coffee experts) and descriptive sensory 51 analysis with trained panelists, leading the authors to the conclusions that 52 these two approaches are not interchangeable. 53

Another notable difference from sensory evaluation is that the quality judgments in cupping combine an overall quality scale (presumably reflecting consumer dislikes) with diagnostic information about defects, whereas in mainstream sensory evaluation these two functions (descriptive and consumer) would be typically separated in two distinct tests with different respondents (Lawless and Heymann, 2010). Assuming that the opinion of a single (or a few) expert can effectively predict consumer preferences is extremely questionable: in fact, particularly for coffee, recent evidence indi-

¹Shortly after this study was conducted, a standardized vocabulary for coffee evaluation had just been released based on a comprehensive work carried out at Kansas State University (https://worldcoffeeresearch.org/work/sensory-lexicon/).

cates that quality evaluations performed by coffee experts do not necessarily
 correspond to consumer preferences (Giacalone et al., 2016).

A final problematic aspect with cupping protocols is the use of holistic quality attributes that rely substantially more on the experts' product knowledge and expectations regarding what is desirable in a coffee (similar to typicality judgments for wine), rather than on clearly defined sensory properties.

⁶⁹ 1.2. Motivation for the present study

One quality attribute that has recently gained attention is the concept 70 of 'clean cup' or 'cleanliness', which has been used in the scientific literature 71 as a sensory attribute for coffee (Ribeiro et al., 2011, 2012), and which is 72 now included in the most important cupping protocols (ISO, 2008; SCAA, 73 2009). The attribute is not related to sanitary aspects (despite what the 74 name might suggest), but is instead used as a quality attribute related to 75 the absence of absence of flaws/defects, which is purportedly associated to 76 consumer preferences. 77

Situated within this context, the aim of this study was to understand 78 the compositional and sensory basis of common roasting defects in coffee, as 79 well as their relation with consumers' perception and preferences. Altough 80 defects in coffee may arise from different sources (indeed, concepts like 'clean 81 cup' are most often associated with quality control of green coffee by experts 82 (Feria-Morales, 2002)), we chose to focus on defects related to the roasting 83 process resulting in off-flavours in the coffee brew, as previous research has 84 shown that coffee's distinct aroma profile is very closely related to the time-85 temperature profiles used during the roasting (Baggenstoss et al., 2008; Masi 86 et al., 2013; Fisk et al., 2012; Yang et al., 2016). 87

Specifically, the chosen strategy was to focus on six distinct roasting profiles, obtained by varying time and temperature in the roasting process (see section 2.1). One of them was roasted to represent a standard roast free of defects, according to recommendations of the Specialty Coffee Association of Europe (Münchow, 2016). The remaining five represented instead roast defects commonly found in the marketplace.

Moreover, this study extends a previous investigation in which the aroma volatile composition of coffee brewed from these six roasting profiles was documented (Yang et al., 2016). The goal of this earlier work was to investigate the formation of aroma compounds in these different time-temperature profiles, in order to identify marker compounds associated with each defect.

⁹⁹ Due to the complexity of aroma interactions, it is however uncertain whether ¹⁰⁰ those chemical changes correspond to perceptually relevant differences in the ¹⁰¹ coffee. Thus, in the present paper, we continue this line of work by presenting ¹⁰² the following new data and analyses:

- A perceptual characterization of the same coffee samples by sensory descriptive analysis, in order to document the sensory properties associated with each roasting profile, as well as to look at the differentiation between the Normal roast and the defects;
- An exploration of the relationship between the instrumental and sensory data, in order to evaluate the degree to which the aroma composition is predictive of the perceptual quality of the coffee;
- A consumer test focusing on consumer perception and liking of coffee
 brewed from the different roasting profiles, carried out to understand
 whether absence of defects bears any correspondence with actual consumer preferences for coffee.

¹¹⁴ 2. Materials and methods

115 2.1. Roasting profiles

The coffee used in the study was a single-origin washed Kenyan Arabica 116 from the wet mill Ndaroini, from crop year 2012/2013 and 2013/2014. The 117 beans were roasted using a Probat drum roaster (Probat–Werke, Germany) 118 modified to include additional temperature sensors to monitor bean temper-119 ature. Due to the limited batch size of the Probat roaster (1 kg), the coffee 120 was roasted on two separate occasions: one batch for the sensory evaluation, 121 and one batch for the consumer and aroma analysis. The coffee beans sam-122 ples were individually packed in odor-free air-tight package, and kept in a 123 cold storage at 5 °C. 124

Six different roasting profiles were obtained by varying start tempera-125 ture and roasting time. Five of the roasting profiles were created to obtain 126 common roasting defects, whereas the last served as a control ('Normal') 127 roast. These roasting profiles were developed by a panel of six coffee experts from the Specialty Coffee Association of Europe (SCAE), headed by the last 129 author, to be part of SCAE roasting certification system, which provides a 130 systematic framework for evaluation of roasting defects (Münchow, 2016). 131 They were designed by modulating the roasting process on three different 132 dimensions: roasting degree, time before 'first crack' (when a popping sound 133

Table 1: Roasting conditions for the six roasting profiles. ^{*a*}Air temperature when the beans entered the roaster; ^{*b*}Time from 'first crack' to the end of the roast; ^{*c*}Spectrophotometric measure indicating the color of the roast (smaller numbers indicate darker roasts)

is first heard during roast), and time after first crack, which represent the
roasting phases were the beans undergo significant the most significant chemical and physical changes - see Schenker et al. (1999, 2000) for an overview.

¹³⁷ A visual representation of the variation in time-temperature profiles is given

¹³⁸ in Figure 1, whereas detailed roasting conditions are reported in Table 1.

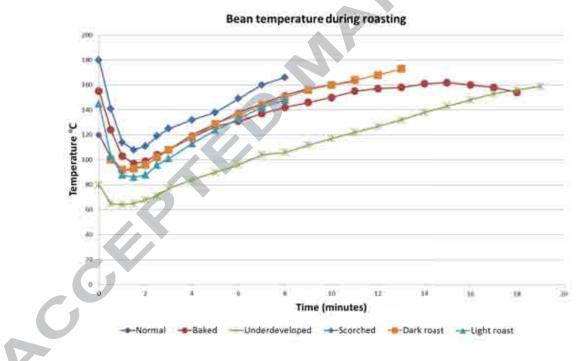

Figure 1: Plot of temperature development over time for the six roasting profiles

¹³⁹ The main characteristics of the six roast profiles are the following:

• Normal. A reference coffee roast with time-temperature profile according to roasting guidelines of the Specialty Coffee Association of Europe

(Münchow, 2016) with respect to initial temperature, developing time and total roasting time (Table 1). The coffee attained the highest 'Clean Cup' grade (10) by an experienced coffee roaster (author MM).

• *Light.* This roast defect has a temperature curve similar to the normal 145 roast, but the roasting process was stopped about 4 min earlier, result-146 ing in a shorter development time (Table 1). This prevented full aroma 147 development from occurring. Accordingly, Yang et al. (2016) found a 148 reduction in most volatile compounds for this sample compared to the 149 Normal roast, with the exception of the heterocyclic compound indole 150 (flowery, mothball-like), which was proposed as chemical marker for 151 this defect. 152

• Scorched. The roasting process for this defect closely resembles that of 153 the Normal roast profile, but it was quicker and at a higher temper-154 ature (Figure 1). This high temperature-short time combination was 155 found to cause a major change in aroma composition compared to the 156 Normal roast. In particular, higher levels of the compounds 4-Ethyl-157 2-methoxyphenol, pyridine, phenol and difurfuryl ether (Yang et al., 158 2016). According to the known properties of these compounds, the 159 coffee brewed from this roast could expectedly be described as smoky, 160 burnt, roasted, bitter and astringent. 161

• *Baked*. The Baked roast had a temperature curve that start at a higher initial temperature in the bean compared to the Normal roast, and its roasting time lasted about 6 minutes longer (Table 1). The resulting aroma profile revealed a slight increase in most aroma compounds compared to the Normal roast, with the largest increase found for the 166 compounds maltol (caramel-like), difurfuryl ether (roasted), and pyridine (roasted, burnt) (Yang et al., 2016).

Underdeveloped. In this defect, the coffee was roasted at a much lower initial temperature $(135^{\circ}C)$ and for 8 minutes longer than the Normal roast. In the authors' intention, the stalling of the temperature curve at the beginning of the roast should have prevented the development of many of the characterizing coffee aromas. This should have resulted in a flat, slightly sour coffee. Nevertheless, Yang et al. (2016) found that, despite the lower initial temperature, the relative abundance of most

- 173 174
- 175

compounds was comparable to that of the Normal roast. It is thus expected that these two samples would be close from a perceptual point of view. The main difference with the Normal roast was the higher concentration of the compound 2,5-dimethylfuran (ether-like odor) (Yang et al., 2016).

Dark. Finally, the Dark defect was roasted with a temperature curve similar to the normal roast, but for 2 minutes longer. As for the Scorched roast, this resulted in a general increase in aroma compounds compared to the Normal roast, most notably in the phenolic compounds 4-Ethyl-2-methoxyphenol and phenol (Yang et al., 2016). This would expectedly results in a coffee brew that could described as smoky or burnt.

All in all, the sample space obtained can be sees as reflecting a consensus representation among coffee professionsals of common roasting defects, whereas the Normal reference would be regarded as clean (free of defects). Admittedly, the definition of the six roasting profiles took as point of departure current roasting practises in the European market (especially Northern Europe), and may not necessarily apply to other geographical regions where e.g. darker or lighter roasts may be more common.

195 2.2. Brewing

Sample preparation for the GC-MS analysis is described in Yang et al.
 (2016). This section describes brewing procedures using in relation to the
 sensory and consumer tests.

The packaged coffee beans were ground the day of serving using an elec-199 tronic coffee grinder (KG 49, Delonghi, Austria), approximately three hours 200 prior to tasting. The coffee was brewed using French press brewers (3 Cup 201 Black Cafetiere, Argos, UK) by adding 50g (+/-0.5g) of coarse ground cof-202 fee to 900g (+/-5g) water. The hot water (approximately $95^{\circ}C$) was poured 203 over the grounds and the plunger was pressed down after 4 minutes and 204 then decanted. 100 ml coffee was poured into each porcelain cup and the 205 coffee settled in the cups in Thermaks cabinets at 22°C to a temperature 206 of $60^{\circ}C$ (+/- 1°C) at which it was served. For the consumer test the coffee 207 was held in thermos prior to serving for no more than 60 minutes before 208 100 ml was poured into each porcelain cup and settled to a temperature of 209 $60^{\circ}C (+/-1^{\circ})$ at which it was served. The thermos was labelled with sam-210 ple number and the same flask was used only for that sample throughout 211

the entire test period. From the literature various serving temperatures for 212 coffee are suggested. There seems to be consensus of a serving temperature 213 in the range of 80-85°C among established coffee authorities and producers. 214 (Merrild, n.d.; National Coffee Association of America, n.d.), whereas several 215 different consumer studies reveals that most consumers prefer a serving tem-216 perature between 60 and 70°C (Borchgrevink et al., 1999; Lee and O'Mahony, 217 2002). The temperature of 60°C was chosen as it is low enough not to in-218 duce scalding hazards (Brown and Diller, 2008) and also represents the same 219 temperature as the coffee would normally be consumed by the consumer. 220

221 2.3. Aroma composition analysis (GC-MS)

Analyses of volatile aroma compounds was conducted using a trace 1300 Gas Chromatograph-Mass Spectrometer (Thermo Fisher Scientific, Hemel Hemptead, UK). Volatiles were identified by comparing their mass spectrum with that of authentic compounds and/or with spectra in reference libraries. Concentrations was calculated with use from the internal standard and expressed in ppb. We refer the reader to Yang et al. (2016) for the detailed protocol used for the GC-MS analysis.

229 2.4. Sensory descriptive analysis

A descriptive analysis was carried out based on the principles of the Quan-230 titative Descriptive Analysis. Nine assessors were recruited from the sensory 231 panel at the University of Copenhagen. All assessors had been screened for 232 sensory acuity and availability prior to inclusion in the sensory panel and were 233 experienced in sensory evaluation of food prior to the study. The profiling 234 took place in the sensory laboratory of University of Copenhagen standard-235 ized after ISO guidelines (ISO 8589:2007) and following good sensory practice 236 (Lawless and Heymann, 2010). 237

The panel was instructed to evaluate the samples by the cupping method, 238 where the coffee is aspirated into the mouth from a spoon (SCAA, 2009). As-239 sessors were instructed to cleanse the mouth with plain white toast bread, 240 milk and tepid water before the first and between each sample. All samples 241 was served warm at a temperature of $60^{\circ}C$ (+/- 1°C) in porcelain cups, blind 242 labelled and with a three digit code. The profiling was carried out over four 243 consecutive days (two days of training and two days of evaluation). The as-244 sessors initially generated their own attributes, and were later supplemented 245 with a list of potential attributes and references to help the panel reach con-246 sensus on the meaning on the attributes. The final set of attributes and the 247

Table 2: Final set of attributes developed for the DA with corresponding scale anchors and reference material

associated references are reported in Table 2. The coffee samples were rated
on a 15 cm unstructured line scale using the FIZZ software (Biosystemes).
The coffee was evaluated in individual sensory booths using a randomized
block design for the serving order, whereby each assessors evaluated each
sample three times.

253 2.5. Consumer test

Eighty-three regular coffee consumers (40 males and 43 women, aged 18-70) participated in the test on a voluntary basis. Consumers were served the six samples monadically. The serving order was randomized across consumers following a balanced block design.

Unlike the trained panel, the consumers did not receive any specific in-258 structions other than to drink the coffee as they would normally do. For each 259 sample, they were first asked to rate the overall liking on a 9-point hedonic 260 scale, and then to complete a check-all-that-apply (CATA) question. The 261 latter consisted of 30 attributes, including both sensory and hedonic terms 262 (the full list is visible in Table 6). The order in which the CATA attributes 263 appeared on the ballots was randomized both *between* and *within* assessors 264 to minimize possible order biases (Ares and Jaeger, 2013). At the end of 265 the test, participants were asked to fill in a questionnaire with background 266 information concerning their demographic and coffee habits (Table 3). 267

1 to 6 cups a day	13
< 1 cup a week	5

Table 3: Information on the consumer sample who participated in the study (N = 83).

The evaluations took place at the Department of Food Science, University of Copenhagen, in a well-lit air-conditioned room at a temperature around 270 22-24°C. On average, consumers used approximately 30 minutes to complete 271 the test.

272 2.6. Data analysis

All analyses were performed in R (Team, 2014) using either native functions or functions from the packages FactoMineR (Lê et al., 2008) and RVAide Memoire (Hervé, 2015). For analyses of inferential nature, the usual $\alpha = 0.05$ level for statistical significance was considered.

277 2.6.1. Sensory descriptive analysis

Differences in mean ratings between the samples in each of the sensory 278 attributes were assessed by ANalysis Of VAriance (ANOVA) using a mixed 279 model with sample and replicate as fixed effects, and assessors as random. 280 When significant fixed effects were found, the ANOVA was followed by post-281 hoc comparison by Tukey's Honestly Significant Difference test. To enable 282 a visual exploration of the sensory results, Principal Component Analysis 283 (PCA) was performed on the significant sensory attributes using data aver-284 aged across both replications and assessors. The data were mean-centered 285

and scaled column-wise (i.e., values were multiplied by the inverse of the
standard deviation for that attribute) prior to the computation of the PCA
model.

2.6.2. Relationships between sensory and instrumental aroma measurements 289 In order to explore relationships between the aroma composition and the 290 sensory data, a Multiple Factor Analysis (MFA) (Husson et al., 2005) was 291 conducted using two inputs matrices: one containing aroma compounds con-292 centrations, and one containing sensory attributes. Both datasets contained 293 data averaged across samples and only included compounds and sensory at-294 tributes that significantly discriminated between the samples assessed by 295 ANOVA². 296

297 2.6.3. Consumer data: Liking and CATA evaluations

A mixed model ANOVA was performed to uncover differences in mean 298 liking ratings between the samples. The model included sample as fixed effect 299 and consumer as random, and was followed by pairwise comparisons by Tukey 300 Honestly Significant Difference (HSD). The CATA responses where rendered 301 as a dichotomous data where a value of 1 indicated that an attribute had been 302 checked and a value of 0 indicated the opposite. Differences between samples 303 with respect to frequency of mention on each individual CATA attribute 304 were assessed using Cochran's Q Test, as customary for this type of data 305 (Meyners et al., 2013). To visualize the frequency of associations of samples 306 with the CATA attributes a correspondence analysis was performed on the 307 contingency table. 308

309 3. Results

310 3.1. Sensory descriptive analysis

Table 4 shows the results of the ANOVA analyses on the DA data. All but two attributes (*nutty* and *caramel*) were found to significantly discriminate between the samples.

The PCA scores and loadings plot for the model using averaged DA data are shown in Figure 2 and Figure 3, respectively. The first two model dimension accounted for high proportion of the variance (over 95%) in the sensory profiles, indicating a clear variance structure in the data.

 $^{^{2}}$ ANOVA results for the GC-MS data are shown in Yang et al. (2016)

Table 4: Mean ratings (15 cm unstructed scale) for each sensory attributes for each of the six roasting profiles. The last two columns show the F value for the sample effect from the corresponding ANOVA model and the associated p value (n.s.= not significant; * p < 0.05; ** p < 0.01; *** p < 0.001). Within rows, means not sharing superscript letters are significantly different (p < 0.05), following pairwise comparison by Tukey HSD test. Attributes are ranked by decreasing size of the F statistic, i.e. by most to least discriminating attribute.

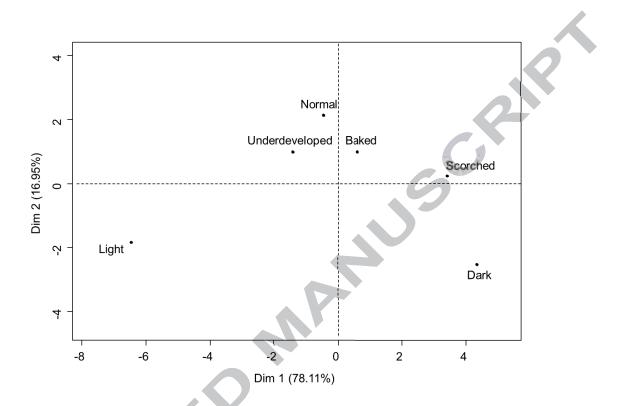

Figure 2: Scores plot showing relative sensory differences between the samples on the first two PCA dimensions.

The first PCA dimension mainly differentiated between the Light on one 318 end, and the Dark and Scorched Roast on the other (Figure 2). The Dark and 319 Scorched sample were associated to the attributes Intensity, Bitter, Bitter 320 (Aftertaste), Astringent, Burnt, Burnt (Aftertaste), Licorice, and Tobacco -321 many of these attributes can be linked to a higher degree of roast, lending 322 face validity to this opposition. Conversely, the Light sample was rated 323 significantly lower in these attributes (Table 4), and was instead primarily 324 associated with the attributes *Citrus*, *Sweet*, and *Roasted Ryebread* (Figures 325 2 and 3). The association of these sensory attributes with the Light sample 326 would suggest that these flavor notes may already be present in the bean, 327 or formed very early in the roasting process. The Light sample was the 328 most singled out in the first dimension Figure 2. It generally obtained lower 329 mean rating than the other samples in all remaining attributes, which would 330

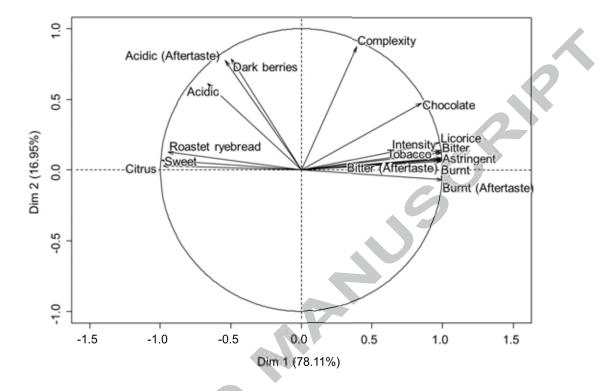

Figure 3: Correlation of sensory attributes with the first two PCA dimensions.

³³¹ suggest that most of the sensory variation is due to the roasting process.
³³² The remaining three samples (Normal, Baked, and Underdeveloped) were
³³³ not well described by the first dimension. Their position close to center of the
³³⁴ plot, as well as inspection of Table 4, indicates that these samples generally
³³⁵ received ratings close to the grand mean of the attributes described by the
³³⁶ first dimension.

These three samples were better discriminated by the second model di-337 mension, which mostly described variation in the attributes *Complexity*, 338 Acidic, Acidic (Aftertaste), and Dark Berries. The Normal roast had the 339 largest positive score on this dimension and, accordingly, received the highest 340 mean ratings in these attributes. However, pairwise comparisons (Table 4) 341 indicated that the difference with the other two samples positively loaded on 342 this dimension (Baked and Underdeveloped) was not statistically significant. 343 The second dimension also highlighted differences between the Scorched and 344 the Dark sample (Figure 2), which had nearly identical position on the first 345 dimension. Their distance on the second dimension was due to slight dif-346

ferences on the attributes *Acidity*, *Acidity* (*Aftertaste*), *Chocolate*, and *Dark Berries*, where the Dark roast had lower mean ratings. The differences in acidity could be attributed to additional acid degradation associated with the longer roasting time for the Dark sample. Generally speaking, the DA results corresponded with the definitions of the roasting profiles from Section 2.1.

353 3.2. Sensory-instrumental relationships

The GC-MS results have previously been reported in Yang et al. (2016), to which we refer the reader for in-depth analysis on the aroma profiles of individual roast defects. In this section, we will focus on exploring instrumental– sensory correlations modeled by MFA.

The main outputs of this analysis are shown in Figures 4 and 5, whereas 358 a full numerical account of the contribution of each variable to the MFA 350 model is given in the appendix to this paper. As in the previous PCA model, 360 two dimensions accounted for over 85% of the original variance. The prod-361 uct space obtained is shown in Figure 4 which also included partial points 362 obtained by considering the two input matrices separately. The plot shows 363 that the aroma and sensory data produced nearly identical product spaces. 364 The only noteworthy difference concerned the distance between the samples 365 Dark and Scorched, which the panel perceived as very close perceptually, 366 whereas in the aroma data they are quite strongly differentiated on the first 367 dimension (Figure 4, see also Figure 2). 368

The first MFA dimension again related to the opposition of the Light vs. 369 the Scorched and Dark roasts. The MFA loadings plot (Figure 5) indicates 370 that this was due to a general increase in aroma compound concentrations 371 associated with the Scorched roast, which was according to expectations (see 372 Section 2.1). The vast majority of the aroma compounds appear bundled in 373 a tight cluster - including mostly pyrazines, aldehydes, alcohols, sulphides, 374 pyrrols, and furans - positively correlated with the first MFA dimension. As 375 we have seen, from a sensory point of view these resulted in an increase in 376 the intensity of several attributes related to the higher degree of roast. The 377 sensory attributes Burnt, Astringent and Burnt (Aftertaste) also correlated 378 highly with the first dimensions, which could be due to high concentrations 379 of pyridine and furfuryl alcohol. 380

The second MFA dimensions separated the Dark roast, and to a lesser extent the Normal roast, from the Light and the Scorched roasts. This direction was mainly associated with variation in the concentration of organic acids

(acetic acid, butanoic acid, hexanoic acid) and, correspondingly, variation in
 acidity (Figure 5).

In spite of a general agreement regarding relative sample differences, some 386 differences between the datasets are observable; for instance, we can see that 387 aroma data do not seem to explain the sensory attributes on the left side of 388 Figure 5 and that there are no sensory attributes correlated to the compounds 389 at the bottom of the same plot. This inconsistency could be due to different 390 factors. For some of the volatiles on the bottom of the plot it may be due to 391 their presence at subthreshold level and/or to limitations in the attribute list 392 that did not include specific odors commonly associated with these volatiles. 393 This is quite possibly the case for furfural (almond-like) and 2,3-pentanedione 394 (buttery). For sensory attributes located on the left side of the plot, the fact 395 that there are no associated volatiles associated might be due to suppression 396 effects. Recall that the left end of the plot is defined by the sample Light 397 and mostly reflects the fact that this sample has the lowest concentration of 398 nearly all aroma compounds. Lower concentrations of aroma compounds may 390 have made some sensory attributes (sweetness and acidity in particular) more 400 prominent in the Light sample, regardless of absolute values. For example, 401 the sample Underdeveloped had the highest concentration of Acedic acid 402 (41.64 ppm), much higher than both Light (20.72 ppm) and Normal (31.04 ppm)403 ppm), yet looking at Table 4 reveals that it was not different from those 404 samples in terms of perceived acidity. 405

406 3.3. Consumer perception of the coffee samples

Mean hedonic ratings for the six roasts are reported in Table 5. ANOVA results revealed a significant main effect of sample on liking $(F_{(5,492)} = 7.7, p < .001)$. As expected, the Normal roast obtained the highest liking ratings, whereas the Light roast was the least liked (Table 5). The range of the consumer liking ratings was not very large (Min: 4.2, Max: 6). However, it is worth noting that there was a statistically significant difference between the Normal roast and all other samples, except for Baked.

Table 6 reports the frequency of occurrence of each CATA attributes across the six samples. All terms were used at least once for each sample. Even the attribute with the lowest occurrence (*Grass*) was used 38 times, indicating that all the attributes were relevant to the consumers. Significant differences between the samples were found for 20 out the 30 CATA attributes. The three most discriminating CATA attributes were *Thin*, *Strong*, and *Mild*.

	Mean	St. Dev.
Normal	6.0^{a}	1.8
Baked	5.7^{ab}	1.9
Scorched	5.6^{bc}	2.2
Underdeveloped	5.4^{bc}	2.0
Dark	5.1^{c}	2.2
Light	4.2^{d}	2.1

Table 5: Mean liking (9-pt hedonic scale) and standard deviation for the six samples ($N =$
83). Means not sharing superscript letters are significantly different (Tukey $p < 0.05$).

The associations between samples and CATA attributes are visually summarized in Figure 6, which shows the bi-plot of the CA performed on the CATA contingency matrix (two dimensions retained, 93.55% of explained variance). Comparing this plot with Figure 2, it is easy to see that the consumers generated a sensory space almost identical to that of the trained assessors³.

Again, the first model dimension describes variation between the Light 427 and the Dark samples. The Dark sample was again associated with attributes 428 related to the darker degree of roast (e.g., Tobacco, Burnt, Sharp, Long af-429 *tertaste*, *Bitter*). This sample was also perceived as the most intense (higest 430 in attribute Strong and Intense, see Table 6) to such an extent that it is also 431 described as *Unpleasant* by the consumers. The Scorched sample lies close to 432 the Dark sample in the first CA dimension. As in the panel data, these two 433 samples are associated with the same attributes, although they are better 434 differentiated here due to the fact that the Scorched sample was generally 435 perceived as less intense than in the Dark (Table 6). With respect to the 436 differences between these two samples, the product space obtained from the 437 CATA data are therefore in line with the indications of the aroma data. The 438 Light sample lies in the opposite direction in the first dimension (Figure 6), 439 and appears as the most different from all others. Like the trained panelists, 440 consumers perceived it as the sweetest and less intense tasting of all sam-441 ples and, additionally, associated this samples with the attributes *Thin* and 442

³The ranking of the samples on the two dimension is reversed compared to Figure 2. However, this is accidental and irrelevant to the interpretation as the focus of both models is on *relative* differences between the samples.

Table 6: Contingency table showing the frequency of mention of each CATA attribute for each of the six roasting profiles. The last two columns report the test statistic for Cochran's Q test (Q) and the associated p value (n.s.= not significant; * p < 0.05; ** p < 0.01; *** p < 0.001). Within rows, frequencies not sharing superscript letters are significantly different (p < 0.05), following pairwise comparison by Cochran's Q test. CATA attributes are ranked by decreasing size of the Q statistic, i.e. by most to least discriminating attribute.

⁴⁴³ *Hey/straw* (Figure 6 and Table 6).

Altough accounting for only 9.5% of the data variance, the second CA 444 dimension provided useful information on the differences of the Normal roast 445 (Figure 6). This sample was primarily associated with the attributes Sweet 446 and *Caramel*, and with two holistic attributes with a positive valence, *Pleas*-447 ant and Balanced. The latter associations are interesting as they related to 448 absence of defects, and confirm the indications of the hedonic ratings (Table 449 5). The Normal roast was also the most frequently associated with the at-450 tribute *Harmonic*, though in this case the differences were too close to reach 451 statistical significance (Table 6). 452

The Underdeveloped and Baked roast were again poorly described by the model and showed sensory profiles quite similar to the Normal roast, especially in the first dimension (Figure 6). However, Table 6 shows some significant differences between these two samples and the Normal roast. The Baked sample was perceived as significantly more *Bitter* and less *Sweet* than the Normal, whereas the Underdeveloped roast was perceived as significantly lower in the attributes *Caramel* and *Dark Berries*.

460 4. Discussion

All three datasets (aroma, sensory and consumer) provided consistent 461 indications concerning the main direction of differences between the six sam-462 ples. As previously reported in Yang et al. (2016), the results indicated a sig-463 nificant increase in aroma compound concentration - particularly pyrazines, 464 aldehydes, alcohols, sulphides, pyrrols, and furans - associated with prolonged 465 roasting time and temperature. This is well in line with literature accounts 466 regarding the influence of roasting to aroma formation in coffee (Masi et al., 467 2013). The highest aroma concentrations were found in the samples Dark 468 and, especially, Scorched (Table 1). This was clearly reflected in the cor-469 responding sensory profiles for these samples which were highest in overall 470 sensory intensity, and scored highest in attributes typically associated with 471 the roasting process. 472

The Normal roast generally obtained values close to average with respect to sensory attribute intensity and aroma compounds concentration. The aroma compounds most strongly associated with the Normal roast were organic acids, which resulted in a higher perceived acidity in this sample compared to all others. This ultimately separated this sample from the high intensity roasts (Scorched in particular), were these acids are lost, and where

Maillard compounds and lipid breakdown products abound (Yang et al.,
2016). The Normal roast was also well differentiated from the Light defect, which was perceived as the sweetest and least intense of all samples,
due to the fact that, as per our intentions with this sample, shortening the
development time did not allow full aroma development to occurr.

The Normal roast was instead not well differentiated by the defects Baked and Underdeveloped, which was expected as their aroma composition (particularly in the case of Underdeveloped) was relatively close to that of the Normal roast (Yang et al., 2016). The results are thus inconclusive with respect to the differences between these two samples and the Normal roast, altough it is worth noting that the consumers perceived the Normal roast as significantly sweeter and less bitter than these two defects.

An interesting finding was that the trained panelists rated the Normal 491 roast highest in the holistic attribute *Complexity*. In the sensory litera-492 ture, flavor complexity has been defined as the total number of separate 493 recognizable sensory qualities in a stimulus (Giacalone et al., 2014), and 494 this definition was also used in the training of the panel for this study. 495 Looking at the PCA for the sensory panel data (Figure 3), it would ap-496 pear as though complexity stands in an inverse U-shaped relationship with 497 overall sensory intensity. A quadratic model with intensity as predictor 498 and complexity as response confirmed this intuition as the model obtained⁴ 499 revealed a significant downward slope associated with the quadratic term 500 $(F(2,3) = 7.86, p \neq 0.06; R^2 = 0.83)$. The underlying phenomenon here 501 seems to be that for very low level of intensity complexity is low as there a 502 few recognizable sensory qualities in the stimulus. In our dataset this is the 503 case of the Light sample where the short roasting time prevented the forma-504 tion of many aroma compounds. For high intensity levels complexity is also 505 low as the present of strong sensory inputs may dominate the percept, such 506 as the sample Dark. The Normal roast, characterized by moderate inten-507 sity sensory, can be understood as having an optimal complexity level where 508 many flavors are recognizable but no one flavor is dominating or off-putting. 509 The association between the Normal roast and the CATA attribute *Balanced* 510 observed in the consumer data also supports this interpretation. Overall, the 511 results seem consistent with the expectation that the Normal roast (charac-512 terized by absence of defects and a high 'clean cup' score) would correspond 513

 $^{^{4}}Complexity = -1.74 + 2.29 * Intensity - 0.13 * Intensity^{2}$

to a coffee brew with a fully developed aroma profile but lacking dominating off-flavors.

Importantly, the consumer test results showed that the Normal roast 516 was the most liked, significantly preferred over all other samples, except 517 Baked (although this lack of difference may be due to insufficient statistical 518 power). Even though the observed differences in average liking ratings were 519 not very large, these results do suggest that absence of defects is relevant 520 to consumer liking of coffee. The main implication for the coffee industry 521 is that roasters may be able to pinpoint at specific markers (chemical and 522 sensory) that may be used to set up internal quality control scoring systems 523 (for aspects pertaining to coffee roasting) in both quality control and product 524 development. For instance, in a product development context roasters would 525 first identify an optimal roast degree, based on their own subjective and/or 526 on a consumer test. Then, 'clean cup'-like evaluations can be used internally 527 to further optimize the roasting profiles, e.g. with respect to timing aspects. 528 Because we expect practical applications in the coffee branch to involve a 529 smaller sensory range than the one used in this paper (particularly with 530 respect to visual variation), we strongly recommend that roasters validate 531 their internal evaluations against consumer test results obtained from their 532 target population of interest. 533

Taken overall, the results of this study provide a comprehensive characterization of chemical and perceptual markers associated with common coffee defects, and demonstrate that a 'clean cup' (a coffee without defects) is associated with higher consumer preference. From a sensory scientific point of view, this research indicates that the attribute 'clean cup' describes a coffee of average sensory intensity, high in acidity, and having with many recognizable flavor attributes.

541 4.1. Limitations and future research

We acknowledge several limitations in this research that is important to keep in mind in order to correctly qualify the results. First, the study only used a single origin *Arabica* bean, and thus the conclusions may not readily generalize to other coffee varieties and origin. For example, the specific finding that the Normal roast was high in acidity is almost certainly related to the choice of coffee (Kenyan coffee is supposed to be high in acidity) whereas it may be considered a defect in different varieties (e.g., Sumatran coffee).

⁵⁴⁹ Furthermore, the research only considered defects germane to the roasting ⁵⁵⁰ process, thus not including other important sources of off-flavours in coffee

- e.g., problems related to production, processing, and storage of the green 551 beans (Agresti et al., 2008; Wintgens, 2009). The impact of these defects on 552 the sensory quality of coffee could be a relevant venue for future research. 553 One additional aspect that deserve attention in future research is the het-554 erogeneity in consumer preferences for coffee. Previous studies have shown 555 that coffee is a product for which different consumer segments (in terms 556 of preferences for specific sensory attributes) can be identified (Varela et al., 557 2014). The data collected here also suggest that this is the case. Interestingly, 558 we note that consumer liking ratings (not shown here) were approximately 550 normally distributed for the two best liked sample (Normal and Baked), but 560 rather bi-modal for the two worst liked sample (Dark and Light), with a sig-561 nificant proportion of the consumers giving high liking ratings for these two 562 roasting profiles. Accordingly, Figure 7 shows scores and loadings from an 563 internal preference map obtained by performing a PCA on a matrix contain-564 ing the hedonic scores for the six samples, from which it can be seen that, 565 altough the majority of the consumers' preference vectors are located in the 566 direction of the Normal roast, several consumers are also located in other 567 areas of the plots, inlcuding a sizeable minority expressing high preference 568 for the Light and Dark roasts. We refrained from discussing this aspect in 569 the paper because our sample size is insufficient to attempt a robust seg-570 mentation. However, it is clear that understanding this heterogeneity in 571 relation common coffee defects may be a useful direction for future research. 572 It would especially be interesting to link different preferences to consumers? 573 background. Previous research have pointed at several factors that may con-574 tribute to defining coffee preference segments, including gender (Cristovam 575 et al., 2000), product usage (Masi et al., 2013) and, more recently, physiolog-576 ical differences in terms of taste sensitivity (Hayes et al., 2010; Masi et al., 577 2015) and coffee metabolism rate (Masi et al., 2016).

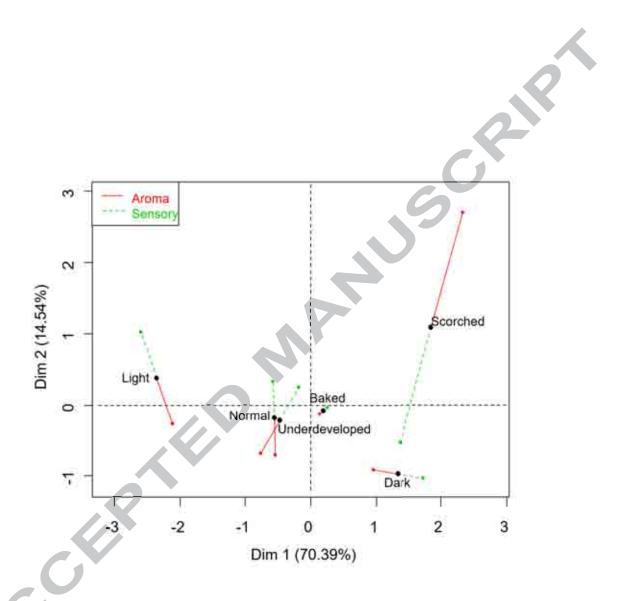

Figure 4: Scores plot showing relative differences between the samples on the first two MFA dimensions. The model is based on both sensory and aroma data and also shows partial points obtained from the two datasets separately.

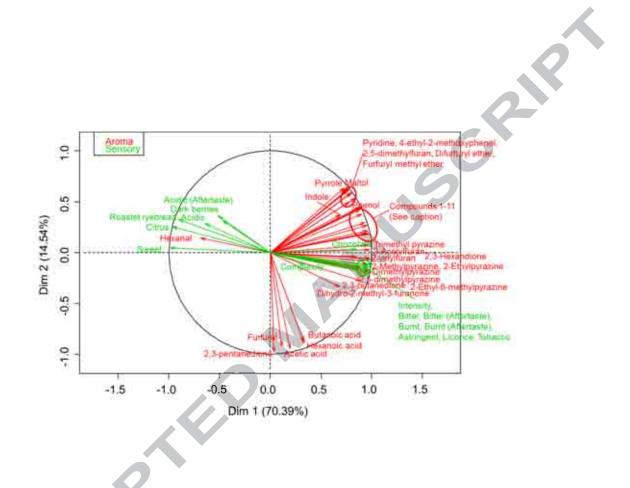

Figure 5: Correlations of the sensory attributes and aroma compounds with the first two MFA dimensions. The unlabeled compounds are the following (ordered by size of correlation with Dim 1): 1) 1-Furfurylpyrrole; 2) Furfuryl alcohol; 3) 2-Methylbutanal; 4) 2,3-dimethyl-Pyrazine; 5) Dimethyl Trisulfide; 6) 3-Methylbutanal; 7) Octanoic acid; 8) 2-Furfuryl methyl disulfide; 9) 1-(1-H-pyrrol-2-yl)ethanone; 10) 3-Methylthiophene; 11) Dimethyl disulfide.

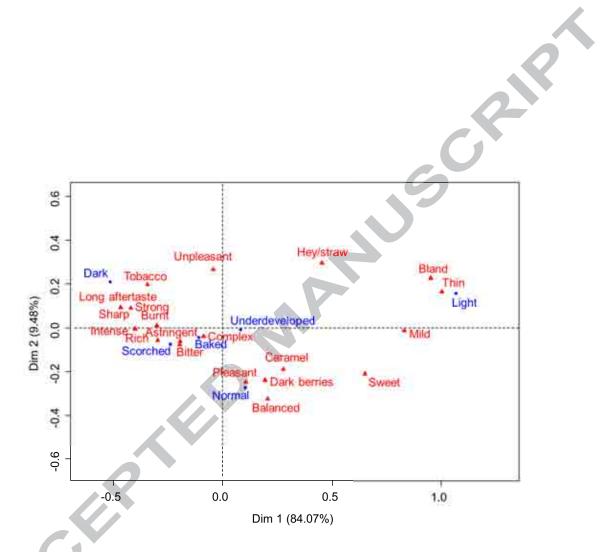

Figure 6: Bi-plot showing associations of samples and CATA attributes on the first two CA dimensions.

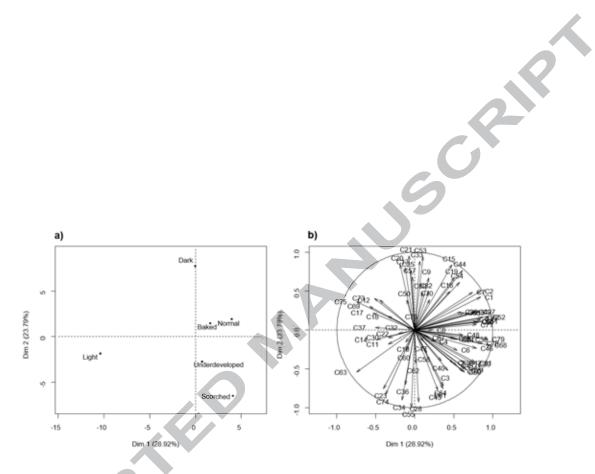

Figure 7: Internal preference map showing the position of the samples based on their hedonic scores (a) and the direction of individual preference for each individual consumer (b).

579 5. Conclusion

This work has investigated common roasting defects in coffee considering compositional (GC-MS), perceptual (sensory descriptive analysis with a trained panel and consumer-based CATA) and affective (consumer liking) aspects. The sensory and GC-MS analyses revealed identical information regarding the overall inter-sample differences, and pointed at at a large influence of the roasting process in the aroma and sensory profiles of the roasts.

The results indicated a significant increase in aroma compound concen-586 tration associated with prolonged roasting time and temperature, resulting 587 in an increase in sensory attributes typically associated with the roasting 588 process - such as Bitter, Astringent, Burnt, Licorice, and Tobacco - as well 589 as to an overall increase in flavor intensity. The Normal roast generally ob-590 tained values close to average with respect to sensory attribute intensity and 591 aroma compounds concentration, consistent with the idea that a coffee with-592 out defects corresponds to a brew with a fully developed aroma profile is 593 related but lacking dominating off-flavors. Supporting this interpretations, 594 consumers described the Normal sample as the most Balanced. Most impor-595 tantly, the Normal coffee obtained the highest consumer liking ratings. 596

Taken overall, these results provide a solid basis for understanding chemical and sensory markers associated with common roasting defects, which coffee professionals may use to set up internal protocols in the context of quality control and product development applications.

601 6. Acknowledgements

We thank Kontra Coffee (Dag Hammarskjolds Alle 36, 2100 Copenhagen, Denmark) for supplying the coffee used in the project and for the use of their roasting equipment. We also thankfully acknowledge the help of Belinda Nielsen, Julie Geertsen and Sarah Østergaard Brandt from University of Copenhagen with preparing the coffee samples for the sensory evaluation.
