TABLE OF CONTENTS

(N.B. In the text Figs. 14-16, Plates 48-53 and Tables 11-20 have been deleted.)

CHAPTER I

INTRODUCTION

At each instar the visible form of the insect body is defined by the cuticle. In the softer parts of the integument the cuticle can unfold and stretch, but in the more inflexible regions, such as the head and appendages, growth cannot occur unless the cuticle is shed. Thus moulting is primarily a mechanism of growth, conditioned by the properties of the cuticle, and serves to allow increase in size and change of form (WIGGLESWORTH, 1965, 1970). Growth implies the production of materials, and in particular proteins, for the formation of the animal (CLARKE, 1965), and is seen to be a continuous process during each instar with only slight discontinuities at ecdysis caused by the loss of the shed cuticle (HIGHNAM and HILL, 1969). The protein requirements for growth are met by the normal food intake and, as CLARKE points out, the link between food intake and growth is of fundamental importance since through it are initiated those physiological mechanisms which will synthesize the nutrients of the food into the specific proteins of the insect's body. The stomatogastric nervous system and the neuroendocrine system constitute this link.

The foregut in insects is innervated by the stomatogastric nervous system (ORLOV, 1924; WILLEY, 1961; CLARKE and LANGLEY, 1963, b, c; DANDO et al., 1968) which is present, in some form or another, in all known insect species (review by CAZAL, 1948). As ROOME (1968) has indicated, the anatomy and function of the stomatogastric nervous system varies according to the mode of feeding of the species concerned. Thus it is generally reduced in liquid feeding insects, where foregut movement is mainly myogenic (JONES, 1960; KNIGHT, 1962), but is more in evidence in insects feeding on solid food stuffs, where movement of the foregut is both myogenic and neurogenic (GRENVILLE, 1962; ROOME, 1968; COOK et al., 1969; MOHL, 1972).

Surprisingly little research has been conducted on the nervous control of foregut movement. In Schistocerca gregaria (CLARKE and GRENVILLE, 1960; GRENVILLE, 1962) movements of the foregut cease altogether after severance of the nerves running from the ingluvial ganglia to the gut. Since the cutting of the outer oesophageal nerves has no effect upon foregut movement these authors conclude that the ingluvial ganglia are autonomous in their effects. According to CLARKE and GRENVILLE the ingluvial ganglia control the contractions of the posterior crop and gizzard, while the hypocerebral ganglion acts by influencing the rate of relaxation of the foregut musculature. The brain and suboesophageal ganglion do not appear to be implicated in the control of foregut movement. Certain regions of the gut, and in particular the oesophagus, display pronounced myogenic activity. ROOME (1968) studied the role of the

stomatogastric nervous system in the control of foregut movement in Locusta migratoria and his results parallel those of the above authors. In addition he found that foregut activity was unaffected by the removal of the frontal ganglion. In Acheta domesticus (MOHL, 1972) the neural mechanism co-ordinating foregut movement is located in the oesophageal nerves, with the hypocerebral and ingluvial ganglia playing merely a stabilizing role.

The involvement of the stomatogastric nervous system in the control of feeding behaviour has been little studied. The results of some ten years' research into the regulation of feeding in the blowfly, Phormia regina, are presented in two reviews (DETHIER, 1969; GELPERIN, 1971). Briefly, food intake in this insect is regulated by the interplay of varying excitatory input from external chemoreceptors and fluctuating feedback from internal mechanoreceptors (stretch receptors) located in the gut and body wall. The stretch receptors are stimulated by the filling of the foregut and their activity, upon arrival at the brain, inhibits the input from the external receptors, resulting in increased taste threshold and consequent cessation of feeding. Information from the foregut receptors is passed to the brain by way of the recurrent nerve. The cutting of this nerve anterior to the stretch receptors interrupts the inhibitory input to the brain and induces hyperphagia. Meal size and the osmotic pressure of the crop contents and blood influence the rate of crop emptying, this process being independent of nervous or endocrine elements.

The stomatogastric nervous system controls crop emptying in Periplaneta and exerts its effect at the level of the proventricular valve (DAVEY and TREHERNE, 1963). The osmotic pressure of the ingested meal, which influences the rate at which the crop empties (TREHERNE, 1957), is detected by a sense organ in the wall of the pharynx. From here information is passed via nerve 5 to the frontal ganglion. A motor pathway, involving the recurrent nerve, the oesophageal nerve and ganglion, and the ingluvial nerve and ganglion, controls the extent and frequency of opening of the proventricular valve. Crop emptying is inhibited when the above pathway is surgically interrupted. In another species of cockroach, Leucophaea maderae, the osmotic values of the food probably do not affect the rate of crop emptying (ENGELMANN, 1968). More important in this respect is the consistency of the food and the initial size of the meal. ENGELMANN considers that the degree of stretch of the crop by the food, and the consistency of the food, is recorded by the stomatogastric nervous system, which in turn controls opening of the proventricular valve via the ingluvial or proventricular ganglion.

The stomatogastric nervous system also controls crop emptying in various acridids, including Schistocerca gregaria (HIGHNAM et al., 1966; HILL et al., 1966); Gryllus bimaculatus (ROUSSEL, 1966); Locusta migratoria (ROOME, 1968); and Melanoplus differentialis (GILLOTT et al., 1970; DOGRA and EWEN, 1971).

In Locusta the stomatogastric nervous system is linked to the cerebral neuroendocrine system by the frontal connectives and, as STRONG (1966) has revealed, by two pairs of fine nerve branches which run from the nervi corporis cardiaci interni to the hypocerebral ganglion.

The insect endocrine system has four major components: groups of neurosecretory cells in the brain, the corpora cardiaca, the corpora allata and the prothoracic glands. Numerous papers have been published on the anatomy and histology of these structures for a wide range of insect groups; some notable reviews are those by CAZAL (1948), WIGGLESWORTH (1964, 1965, 1970), GABE (1966), NOVAK (1966), HERMAN (1967, JOLY (1968) and HIGHNAM and HILL (1969). Particular attention is paid here to the structure of the endocrine system in Locusta.

The cerebral neurosecretory system in acridids has been reviewed by GIRARDIE (1970). In Locusta the neurosecretory cells in each half of the pars intercerebralis form two groups: a medial group (CLARKE and LANGLEY, 1963d; GIRARDIE and GIRARDIE, 1966, 1967) and a lateral group (RAABE, 1964). The medial group contains three cell types: A, B and C (CLARKE, 1966; GIRARDIE and GIRARDIE, 1966, 1967). The majority of the axons from each median neurosecretory cell group decussate within the brain and emerge as the nervus corporis cardiacum internus (NCC I) to enter the contralateral corpus cardiacum. The remaining axons cross over twice and so enter the ipsilateral corpus cardiacum (HIGHNAM, 1969; HIGHNAM and WEST, 1971). The axons

from each lateral neurosecretory cell group constitute the nervus corporis cardiaci externus (NCC II) and run directly to the ipsilateral corpus cardiacum. A third group of protocerebral neurosecretory cells, which are situated below the median ocellus, have recently been described in Locusta and Schistocerca (GIRARDIE, 1970) and Melanoplus (DOGRA and EWEN, 1970). Many insect species, including Locusta, contain a group of neurosecretory cells in each tritocerebral lobe (RAABE, 1963a). The axons of these cells run to the ipsilateral corpus cardiacum as the nervus corporis cardiacum III (NCC III) (RAABE, 1963b). A fourth pair of nerves, the nervi corporis cardiaci IV (NCC IV), which leave the posterior face of the deuterocerebrum and run to the corpora cardiaca, have been described in Locusta, and a number of other insect species, by BROUSSE-GAURY (1967). The cell bodies of these nerves have not been identified in Locusta, but BROUSSE-GAURY has been able to detect a few "Gomori positive" cells in the deuterocerebrum of Dytiscus marginalis which, she believes, may be the perikarya of the NCC IV.

The corpus cardiacum in Locusta has been variously described, both at the light (NAYAR, 1954; OZBAS, 1957b; CLARKE and LANGLEY, 1963d; CASSIER, 1965) and ultrastructural (CASSIER and FAIN-MAUREL, 1970a, b; CAZAL et al., 1971) levels. It is made up of the bulbous endings of the neurosecretory axons from the brain, carried in the NCC I-IV, but also contains intrinsic glandular cells of its own.

Closely associated with the corpus cardiacum is the corpus allatum, whose structure in Locusta has been described at the light level by OZBAS (1957a), JOLY (1960), ANSTEE

(1968) and CLARKE and ANSTEE (1971), and at the ultrastructural level by JOLY et al. (1967, 1968, 1969). The corpus allatum contains numerous glandular cells as well as axon termini derived from the nervus corporis allatum I (NCA I), and nervus corporis allatum II (NCA II). The NCA I links the corpus allatum to the corpus cardiacum, while the NCA II links it to the sub-oesophageal ganglion (STAAL, 1961). Neurosecretory material has been detected in the NCA I (CASSIER and FAIN-MAUREL, 1970b) and NCA II (CHALAYE, 1965, 1966, 1967).

The prothoracic glands in Locusta are composed of a thin sheet of cells lying at the postero-lateral edge of the head capsule (STRICH-HALBWACHS, 1954). Their ultrastructure in the nymphal form has been described by FAIN-MAUREL and CASSIER (1968). CLARKE and LANGLEY (1963a) could find no trace of nerves to the prothoracic glands in Locusta, but according to CHALAYE (1965, 1966) the glands in this insect are innervated by nerves from the sub-oesophageal ganglion. In Leucophaea (SCHARRER, 1964), Calliphora erythrocephala (NORMANN, 1965) and Tenebrio molitor (ROMER, 1971) the nerves innervating the prothoracic glands contain both neurosecretory and non-neurosecretory axons.

There exist numerous examples of the control of metabolic processes, other than moulting, by the secretions of the insect neuroendocrine system (see recent reviews by JOLY and CAZAL, 1969; WIGGLESWORTH, 1970). As early as 1936, WIGGLESWORTH had clearly demonstrated that the corpora allata were essential for the normal maturation of eggs in

adult Rhodnius prolixus. Shortly afterwards PFEIFFER (1939) showed that ablation of the corpora allata in adult Melanoplus prevented egg development beyond the stage at which yolk deposition normally occurred. Since these early discoveries the relationship between corpus allatum activity and egg development has been confirmed in a number of insects (reviews by JOHANSSON, 1958; ENGELMANN, 1968).

THOMSEN (1952) was the first to show that the median neurosecretory cells of the pars intercerebralis are essential for ovarian development and normal reproduction in Calliphora. Many authors have since demonstrated the importance of the neurosecretory cells for the complete development of the oocytes (HIGHNAM, 1962; MORDUE, 1965; LEA, 1967; WILKENS, 1968).

The protein metabolism of the whole insect is also under neurosecretory control. In Calliphora (THOMSEN and MOLLER, 1959, 1963), Tenebrio (MORDUE, 1967) and Melanoplus (DOGRA and GILLOTT, 1971) the neurosecretory hormone regulates midgut protease synthesis. In Schistocerca the neurosecretory cells of the pars intercerebralis and corpora cardiaca exert a controlling influence over the protein content of the haemolymph and the protein synthetic activity of the fat body (HILL, 1962, 1965; OSBORNE et al., 1968). A number of workers have also implicated the corpora allata in the control of protein synthesis (BODENSTEIN, 1953; L'HELIAS, 1957; ROLLER, 1962; MINKS, 1967).

Neurosecretory factors influence many other body processes including: excretion and water balance (MADDRELL, 1963, 1964; BERRIDGE, 1966; CAZAL and GIRARDIE, 1968;

MORDUE, 1969, 1970), cuticular hardening and darkening (FRAENKEL and HSIAO, 1965), gut contractions (review by DAVEY, 1964; CAZAL, 1969), rate of heart beat (CAMERON, 1953; DAVEY, 1961; MORDUE and GOLDSWORTHY, 1969), blood sugar level (STEELE, 1961, 1963; MORDUE and GOLDSWORTHY, 1969) and pigmentation (RAABE, 1963c; GIRARDIE, 1967).

A natural outcome of the study of insect neuroendocrine function has been the discovery of a variety of stimuli for initiating neurosecretory activity. One of the most important of these is feeding. A single blood meal stimulates the release of neurosecretion in Rhodnius, the stimulus reaching the cerebral neuroendocrine system via the central nervous system (WIGGLESWORTH, 1934; VAN DER KLOOT, 1960, 1961). When starved Schistocerca (HIGHNAM et al., 1966), Locusta (HIGHNAM and WEST, 1971) or Melanoplus (DOGRA and GILLOTT, 1971) are allowed to feed there follows a fairly rapid depletion of the accumulated stainable material from the neurosecretory system. This suggests the involvement of a direct control mechanism, perhaps via chemoreceptors situated on the posterior surface of the labrum (DAVEY, 1961, 1962a, b) or via foregut stretch receptors (CLARKE and LANGLEY, 1963c).

A variety of environmental factors affect neurosecretory activity in insects. The studies of LEES (1964) and WILLIAMS and ADKISSON (1964) strongly suggest that light has a direct effect on the medial neurosecretory cells. Further evidence for this stems from the work of CYMBOROWSKI and DUTKOWSKI (1969, 1970). COOK and MILLIGAN (1972) have shown

that light can affect both the 'resting' and spike potentials of the median neurosecretory cells in Periplaneta, and they suggest that this might cause changes in synthesis and/or secretory activity of these cells. The photo-neuroendocrine pathways influencing the activity of the cerebral neurosecretory centres in cockroaches have been traced by BROUSSE-GAURY (1968a, b, 1969a). Here, fibres of ocellar nerves synapse with neurosecretory perikarya of the cerebral ganglion whose axons comprise the NCC I, II and IV. The neurone cell bodies of the latter nerve also receive sensory input from the antenna (BROUSSE-GAURY, 1968c), while those of the NCC III synapse with the labral nerve (BROUSSE-GAURY, 1969b). CLARKE (1966) has shown that temperature can affect the amount of material present in the corpora cardiaca. Thus, in 6 day-old adult Locusta the amount of neurosecretory 'A' material in the anterior lobes at 15°C is less than at 30°C or 45°C. Widely fluctuating temperature regimes (e.g. 30° $\pm$ 15°C) have a more dramatic effect upon the corpora cardiaca, leaving them completely depleted of neurosecretory material.

Other naturally occurring phenomena that bring about the rapid release of material from the neurosecretory system include copulation (HIGHNAM, 1961, 1962; HIGHNAM and LUSIS, 1962), oviposition (HIGHNAM, 1962), and flying (HIGHNAM and HASKELL, 1964). Neurosecretory release can also be induced by artificial means, as for example by electrical stimulation (HODGSON and GELDIAY, 1959; HIGHNAM, 1961, 1962; SCHARRER and KATER, 1969; NORMANN, 1969), enforced activity (HODGSON and GELDIAY, 1959; HIGHNAM, 1961, 1962) or drastic wounding (HIGHNAM, 1962).

It is not known for certain what causes the discharge of neurosecretory material from its intraneuronal storage sites but there are reasons to suppose that this process is correlated with action potentials conducted by neurosecretory neurones (COOKE, 1967; GOSBEE et al., 1968; COOK and MILLIGAN, 1972). The work of BERLIND and COOKE (1968) indicates that the release of neurosecretory material in invertebrates, like that in vertebrates, is a calcium-dependent process. NORMANN (1965) has suggested that neurosecretory granules can only be discharged when a nerve impulse depolarizes the axon membrane and makes it possible for the granule membrane to fuse with the cell membrane. Granule liberation may be achieved either by exocytosis or by intracellular fragmentation (review by SCHARRER and WEITZMAN, 1970).

The historical aspects of the endocrine control of moulting are well known to insect physiologists. KOPEC (1922) was the first to demonstrate that the brain was the source of a hormone necessary for growth and metamorphosis. Subsequent work in other Lepidoptera by HACHLOW (1931) indicated that a region in the thorax was controlling growth and metamorphosis. Nine years later FUKUDA (1940) proved that the 'prothoracic glands' in larvae and pupae of Bombyx mori were the immediate source of the moulting hormone.

In a series of papers WIGGLESWORTH (1934, 1939, 1940) showed that the neurosecretory cells of the pars intercerebralis produce a hormone which initiates moulting in Rhodnius, and that the corpora allata normally furnish a "metamorphosis

inhibiting hormone", the secretion of which fails in the last nymphal instar thus permitting the development of the adult characters at the final moult.

WILLIAMS (1947) proved that the prothoracic glands in Hyolophora cecropia were stimulated by factors from the neurosecretory cells of the brain to secrete their own hormone which brings about the termination of pupal diapause.

Some thirty years after KOPEC's initial discovery WIGGLESWORTH (1952) brought together the available evidence and showed that the "moulting hormone" he had described in 1934 was in fact a composite factor, consisting of an activation hormone from the brain and a moulting hormone from the prothoracic glands.

Since these early studies there have appeared many reviews on the regulation of growth and moulting in insects by the interaction of factors from the brain, corpora allata and prothoracic glands (WIGGLESWORTH, 1957, 1964, 1970; LEES, 1955; VAN DER KLOOT, 1960; DE WILDE, 1962; KARLSON, 1963; SCHNEIDERMAN and GILBERT, 1964; HIGHNAM, 1967; JOLY, 1968).

The manner in which the brain hormone influences the prothoracic glands has been little studied. In Rhodnius (WIGGLESWORTH, 1934) the prothoracic glands must be exposed to the brain hormone for a certain "critical period" in order that the moulting cycle might proceed to completion. This is also the case in Calpodes ethlius (LOCKE, 1970) and in the adult apterygote, Thermobia domestica (WATSON, 1964). Extirpation of the pars intercerebralis (GIRARDIE, 1964) or the prothoracic glands (JOLY et al., 1956; STRICH-HALBWACHS,

1959) in Locusta nymphs before the critical period leads to a permanent arrest of moulting.

In Rhodnius the brain hormone causes the cells of the prothoracic glands to undergo a conspicuous cycle of secretory activity, with the nuclei increasing greatly in size during the critical period. OBERLANDER et al. (1965) have shown autoradiographically that within 12 hr of exposure to brain hormone the prothoracic gland cells in the pupa of Antheraea polyphemus are engaged in active nuclear RNA synthesis. This is followed by the appearance of cytoplasmic RNA and by protein synthesis, events which are taken to represent the synthesis of enzymes necessary for the production of ecdysone (SCHNEIDERMAN and GILBERT, 1964). In Periplaneta the cells of the prothoracic glands are stimulated to synthesize nuclear RNA within 8 hr of brain hormone application (GERSCH and STURZEBECHER, 1970). One of the responses that the prothoracic glands in Locusta make upon the release of the brain hormone is an increase in cell number (CLARKE and LANGLEY, 1963a); another is an increase in nuclear size by some but not all of the gland cells (CARLISLE and ELLIS, 1968).

The moulting hormone exerts its effect upon the epidermal cells by setting in motion an orderly sequence of events which occur synchronously in all parts of the body. This sequence includes apolysis (separation of the cuticle from the underlying epidermis), cell enlargement and associated protein synthesis, secretion of the new cuticle, and resorption of the old cuticle. In the integument of Locusta (JOLY, 1955) a wave of mitoses in the epidermal cells is an integral part of the moulting process; but in Rhodnius (WIGGLESWORTH, 1940, 1963) moulting may occur with almost no mitoses at all.

KARLSON (1956) isolated a pure, chemically defined hormone from pupae of Bombyx and named it ecdysone; but although this hormone initiates the changes in the epidermis normally associated with moulting, its presence in the prothoracic glands has still to be demonstrated. ELLIS et al. (1972) have recently shown that the prothoracic glands in Schistocerca contain two substances which cause apolysis and early stages of moulting to take place, but do not contain a third substance, 20-hydroxyecdysone, which is necessary for the formation of the new cuticle (MORGAN and WOODBRIDGE, 1971). It has been suggested that the prothoracic glands produce another hormone or hormones, which trigger(s) the formation of 20-hydroxyecdysone in another part of the body, possibly the oenocytes of the abdomen (WEIR, 1970; LOCKE, 1969; ROMER, 1971).

As well as being activated by the brain hormone and possibly directly influenced by nervous elements, the prothoracic glands can also be activated by ecdysone itself, a mechanism which perhaps ensures the synchronous secretion of each of the paired glands (WILLIAMS, 1952; WIGGLESWORTH, 1964). Furthermore, the prothoracic glands in certain Lepidoptera can be activated by the corpora allata (GILBERT and SCHNEIDERMAN, 1959; ICHIKAWA and NISHIITSUTSUJI-OWA, 1959; WILLIAMS, 1959; SCHNEIDERMAN and GILBERT, 1964). There is, however, a strong possibility that this effect is a pharmacological one (HERMAN, 1968).

It is clear, then, that the release of the brain hormone is the initial step in a sequence of events that lead up to a moult. But despite the importance of this step, there exist

only a few examples of the stimuli responsible for initiating the release of the brain hormone, and most of these are rather specialized.

On severing the ventral nerve cord in the prothorax of a newly fed nymph of Rhodnius, WIGGLESWORTH (1934) found that the animal would not moult although its endocrine system was still fully intact. He concluded that the stimulus for initiating the moulting cycle was the stretching of the abdomen rather than the animal's state of nutrition, since Rhodnius could live for long periods if fed on small blood meals. VAN DER KLOOT (1961) has since demonstrated the existence of stretch receptors in the abdomen of this insect which, when stimulated, cause impulses to appear in the nervi corporis cardiaci, an effect also produced following stimulation of the ventral nerve cord.

KEMPER (1931) also concluded that distension of the abdomen was important in the initiation of moulting in the bed-bug, Cimex lectularis.

Since in their natural habitat these two insects only occasionally obtain a full blood meal, this method of initiating the moulting cycle must be regarded as a special adaptation.

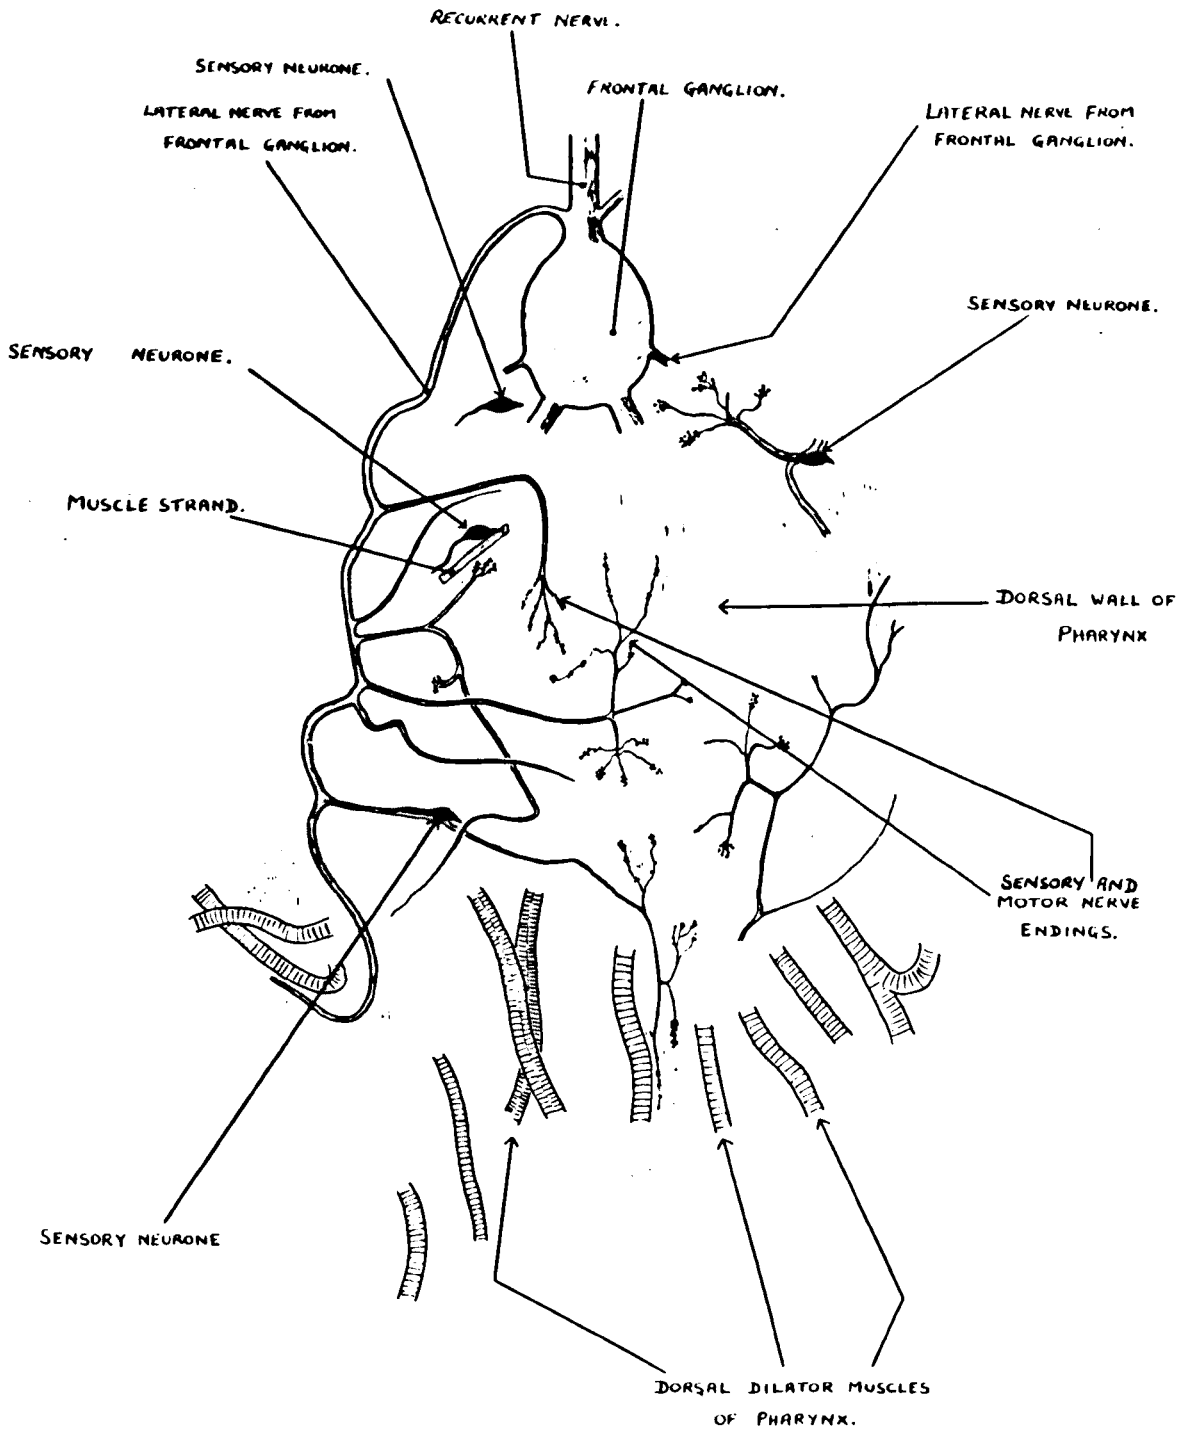
Other known mechanisms for initiating moulting are also rather exceptional. For example, the squash fly, Zeugoducus depressus, which as a larva lives in the cavity fresh fruit, does not undergo pupation until the concentration of carbon dioxide in its environment has fallen from about 6% to 1%, usually after six months storage (TAKAOKA, 1960).

In insects that feed more or less continuously throughout their lives the moult-inducing mechanism has received scant attention. One notable exception is the work of CLARKE and LANGLEY (1963a, b, c, d). During an investigation into the factors which initiate growth and moulting in Locusta, these authors discovered a number of operations which, when performed before a certain critical period, not only prevented moulting, but also arrested growth (LANGLEY, 1962). Since the work to be described in this thesis is, in part, a direct continuation of this investigation, a resumé of the more important results and conclusions is now given.

Methylene blue preparations of the anterior region of the head revealed that, in addition to the three main nerves which leave the frontal ganglion (the two frontal connectives and the recurrent nerve), there were a number of finer nerves associated with the sensory neurones which lie close to the surface of the pharynx (LANGLEY, 1962; CLARKE and LANGLEY, 1962, 1963b, c) (Diagram I). These sensory neurones resembled those described by other workers in the Orthoptera (ZAWARZIN, 1916), Coleoptera (ORLOV, 1924), and Hymenoptera and Lepidoptera (FINLAYSON and LOWENSTEIN, 1958). It thus seemed that the frontal ganglion was well equipped to receive sensory impulses arising from distension and relaxation of the foregut (LANGLEY, 1962).

Following the removal of the frontal ganglion, the cutting of both frontal connectives, or the separation of the frontal ganglion from the surface of the foregut (which involved severance of the anterior and posterior pharyngeal nerves), there was an immediate and irreversible cessation of

DIAGRAM I



INNERVATION OF THE DORSAL PHARYNGEAL WALL FROM THE FRONTAL GANGLION.

(By kind permission of Dr. P. Langley.)

growth, as indicated by body weight. On the other hand, the cutting of the recurrent nerve or only one frontal connective had little or no effect on growth and moulting in the animal (CLARKE and LANGLEY, 1963b, c).

Evidence for the endocrine control of protein metabolism in insects has been indicated above, and it was thought by CLARKE and LANGLEY (1963d) that these "growth arresting operations" might be mediating their effect via the neurosecretory system of the animal on protein metabolism. To test this view they compared the neuroendocrine system of a normal animal with that of an animal subjected to a growth arresting operation (frontal ganglionectomy). The neuroendocrine system in normal animals, examined from the beginning of the third instar until the middle of the fifth instar, revealed no histological signs of a cycle of secretion which could be correlated with the progress of the growth and moulting cycle. The secretory cells of the pars intercerebralis presented a constant picture as too did the corpora cardiaca. Only on rare occasions, and in minute quantities, could neurosecretory material be detected in the NCC I. The neuroendocrine system in frontal ganglionectomised third instar nymphs resembled that in the normal insect for some time after the operation. However, by about 200 hr after the operation the axons of the NCC I had become loaded with neurosecretory material where they emerge from the brain. The corpora cardiaca at this time were abnormal, appearing shrunken and with little sign of cytological detail.

As a result of their studies CLARKE and LANGLEY (1963d) have proposed the following hypothesis of the control of

growth and moulting in locusts:

Throughout a single instar the insect feeds, digests, absorbs and assimilates its food and increases its body tissue content. At this time the foregut is continually being exercised with the passage of food. These distortions of the foregut stimulate the stretch receptors situated on its surface to send nervous impulses to the brain via the posterior pharyngeal nerves, frontal ganglion and frontal connectives, and to the corpora cardiaca via the recurrent nerve and hypocerebral ganglion. On arrival at the brain the nervous impulses stimulate the medial neurosecretory cells of the pars intercerebralis to synthesize, transport, and release their secretions into the blood. During the instar feeding period these secretions exert a controlling influence over food metabolism. Towards the end of the instar the insect ceases to feed prior to moulting (CLARKE, 1956). However, movements of the foregut do not cease, and may even be accentuated, firstly in the process of emptying the gut of food, and secondly in the swallowing of air, which is a necessary preliminary to the shedding of the old cuticle. Therefore, information continues to pass to the brain and more hormone is synthesised and released. Since this hormone is no longer required for the metabolism of food material, its titre in the blood is raised to a critical point at which the prothoracic glands are triggered into activity. After ecdysis, feeding is resumed and the hormone titre falls as the brain hormone becomes involved once more in the control of food metabolism. CLARKE and LANGLEY consider that this

hypothesis can be applied to all continuously feeding insects whose development is not arrested by other phenomena during the course of their life cycles.

The hypothesis is strengthened by the work of CLARKE and GILLOTT (1967a) who demonstrated a marked reduction in protein synthesis, as measured by the incorporation of ^{14}C-glycine into protein, after the removal of the frontal ganglion from third instar Locusta nymphs. In addition, it was shown that the injection of corpora cardiaca extract into frontal ganglionectomised locusts led to a resumption and continuation of growth, indicating that the effects of this operation are mediated through this endocrine organ. At the cellular level CLARKE and GILLOTT (1967b) found that frontal ganglionectomy adversely affected the ability of many tissues to synthesis RNA in the nucleus. They suggest that the two best known effects of the brain hormone, protein synthesis and activation of the prothoracic gland, can be explained by attributing a common function to the brain hormone, namely that of promoting the synthesis of messenger RNA within the cell.

CLARKE and ANSTEE (1971b) report an accumulation of neurosecretory material in the NCC I of frontal ganglionectomised fifth instar Locusta nymphs within 72 hr of the operation, over 100 hr earlier than in the operated third instar nymphs of CLARKE and LANGLEY. At the ultrastructural level, the manufacture of neurosecretory granules by the Golgi bodies appeared to be unaffected by the operation, a result strengthening the view of CLARKE and GILLOTT (1967a) that frontal ganglionectomy acts at the level of neurosecretory

release rather than at the level of neurosecretory synthesis. The cells of the midgut and fat body were found, when examined electron microscopically, to exhibit typical signs of reduced protein synthesis (CLARKE and ANSTEE, 1971a). This is attributed to lack of brain hormone, and possibly also lack of juvenile hormone, since the corpora allata in operated nymphs appear shrunken and histological inactive (CLARKE and ANSTEE, 1971b).

Since the publication of CLARKE and LANGLEY's original series of papers in 1963, a number of investigators have found that frontal ganglionectomy does not always block growth in every operated animal. Thus, while the majority of the frontal ganglionectomised Locusta and Schistocerca nymphs of ROOME (1968) maintained a constant weight after the operation, a few showed fairly significant weight increases and displayed well developed fat bodies at autopsy. According to ROUSSEL (1966) removal of the frontal ganglion from young and mature adults of Necrophorus vespillo has no adverse effect upon growth, the operated animals continuing normal alimentation and increasing their body weight. Protein digestion and syntheis does not stop when the frontal ganglion is removed from adult female Melanoplus (DOGRA and EWEN, 1971), the operated animals laying eggs at a rate equal to about 60% of that for normal mated females. Neither is protein syntheis blocked in frontal ganglionectomised Periplaneta nymphs (PENZLIN, 1971), since these animals continue to regenerate legs in the normal manner after the operation.

Two operations are central to the hypothesis of CLARKE and LANGLEY: the severance of both frontal connectives, and the separation of the frontal ganglion from the surface of the foregut (involving severance of the pharyngeal nerves). Both operations were attended by an early high mortality and the growth curves presented by CLARKE and LANGLEY (1963c) are representative, in each case, of a few animals only. In view of the importance of these two operations, and taking into consideration the above mentioned discrepancies associated with the operation of frontal ganglionectomy, it was considered necessary to repeat all three operations and to check their effect on the growth and moulting cycle in Locusta migratoria migratorioides. In addition the anatomy and fine structure of certain components of the stomatogastric nervous system is investigated, and the results obtained are presented in this thesis.

CHAPTER II

MATERIAL AND METHODS

A. Maintenance of the stock animals

The work to be described in this thesis has been carried out on Locusta migratoria migratorioides R. and F., phase gregaria, stocks of which were originally supplied by the Anti-Locust Research Centre.

The locusts were reared in a centrally heated insectary at a temperature of 28 ± 0.5°C and a relative humidity of 70 ± 5%. Air was circulated through the room by two large electric fans attached to the ceiling; in addition slight continuous air exchange was permitted by two small ventilators. General illumination was provided by five 80 watt fluorescent strip lights.

Populations of Locusta were housed in glass-fronted metal cages of the type recommended by the Anti-Locust Research Centre (HUNTER-JONES, 1961). The area containing the locusts measured 43 cm high x 38 cm wide x 38 cm deep. This was separated from the true base of the cage by a false floor

constructed of perforated plated steel which allowed all faeces, except those of adults, to pass through to the space underneath. The space between the false floor and the true base measured 10 cm. Several circular holes, 4 cm in diameter, were cut into the false floor and into them were inserted aluminium tubes filled with a moist silver sand/peat mixture (75%/25% by volume) for the deposition of egg pods by the sexually mature females. The tubes were replaced daily thus making it possible to define to within 24 hr the age of the eggs (LANGLEY, 1962).

The sides and back of the cage were lined with muslin to increase the area over which the locusts could move. Each cage was illuminated by a single 25 watt light bulb which, together with the general illumination of the insectary, was controlled by a time-switch to give a 12 hr light/12 hr dark period each day. Air circulated freely in and out of the cage via a small perforated area in the roof and the open space between the false perforated floor and the true base. Access to the locusts was by a trapdoor in the roof of the cage. High density cultures were maintained to ensure no reversion to the solitary phase (HUNTER-JONES, 1961).

Freshly picked grass of a good quality was administered every day to the nymphal and sexually mature populations of Locusta. Mortality among newly emerged and maturing adults

was greatly reduced by supplying them with grass picked the previous day and therefore containing less moisture than the freshly picked form. Flake bran was used to augment the grass diet, offering as it does protein without associated water. In Schistocerca adults (HILL et al., 1968) the omission of bran from the diet slows down the rate of somatic growth and delays the onset of oocyte development.

Under the rearing conditions described a pre-adult life span of about four weeks was obtained.

B. Maintenance of the experimental animals

(i) Fourth and fifth instars

Fourth and fifth instar nymphs were kept singly in 8 oz screw-cap glass jars (350 ml capacity) with perforated metal lids. The jars contained a floor and perch of filter paper which served to soak up excess moisture from the grass and faecal pellets as well as any haemolymph escaping from the operation wound. The filter papers were replaced at regular intervals during the course of an experiment.

When moulting was imminent (indicated by a drop in weight and softening of the cuticle) fifth instar experimental animals were transferred to plastic containers measuring

13.5 cm high x 10 cm wide x 10 cm deep. The lids were of gauze with a plastic rim. Each box contained a floor and perch of filter paper, the locusts moulting from either the perch or the gauze of the lid.

Fresh grass was supplied daily in amounts only just exceeding that which could be consumed in a day. Bran was not provided. The experimental nymphs were exposed to the general illumination of the insectary only and, as in the stock cages, the relative humidity of their environment was somewhat variable.

No signs of phase change were apparent in locusts kept individually (CLARKE and GILLOTT, 1967 a).

(ii) Adults

Adults were kept separately in glass jars at room temperature for two days after the operation. They were returned to the insectary on the third day and transferred to an empty stock cage where they spent the rest of the experimental period under crowded conditions. Fresh grass and bran were offered daily.

C. Sampling technique

In order to obtain a uniform population some sort of sampling technique is essential (LANGLEY, 1962). The technique employed was similar to that previously described by GILLOTT (1965), ANSTEE (1968) and ROOME (1968). Let us suppose that fifth instar locusts were required, then once the fourth ecdysis was under way all the fifth instars present in the stock cage were removed each day at 9 a.m. and 5 p.m. This continued until sufficient animals for the particular experiment were obtained at any one sample. During the present study only those nymphs moulting between 5 p.m. and 9 a.m. were used. The age range of the sampled population was therefore 8 hr $\pm$ 8 hr.

Since the ecdysial time range of the fifth ecdysis is the longest (LANGLEY, 1962) it was found necessary to extend the sampling period for adults to 24 hr so that sufficient numbers of locusts could be obtained at a single sample. Newly emerged adults were sampled each day at 9 a.m. thus giving the sampled population an age range of 12 hr $\pm$ 12 hr.

Newly moulted deformed nymphs or fledglings were discarded as were excessively light or heavy locusts; acceptable weight ranges were as follows:

Fourth instar	Male	190-250 mg
	Female	210-280 mg
Fifth instar	Male	400-550 mg
	Female	500-650 mg
Adult	Male	900-1250 mg
	Female	1100-1500 mg

Animals sampled for an experiment were randomly divided into two, and very occasionally three, groups:

(a) Operated animals were subjected to various operations, involving nerve severance, performed on the anterior stomatogastric nervous system or occasionally on the central nervous system. The operations were always carried out during the first 30 hr of the instar.

(b) Control animals were treated in an identical manner to the operated group except that the nerves were merely touched and not cut.

(c) Normal or unoperated control animals were only occasionally used. They were sampled, weighed and then immediately returned to insectary conditions.

D. Anaesthesia

Locusts were anaesthetized in an 8 oz screw top jar containing a cotton wool plug soaked in anaesthetic ether (MacFarlan Smith Ltd.). A narrow layer of cotton wool and a few filter papers were placed on top of the ether plug to prevent the locust coming into direct contact with the liquid anaesthetic. Each animal was anaesthetised for three minutes after which time it had become completely immobile.

E. Sterilization

A fairly rigid sterilization procedure was adopted which, when adhered to, led to a high survival rate among the operated animals. Glass jars were sterilized for 30 min in an autoclave at 250°F (15 pounds per square inch pressure) and instruments exposed to ultra-violet light in a dust-proof cabinet for 30 min immediately before use (CLARKE and LANGLEY, 1963 b). The ringer solution (HOYLE, 1955) used during the operations was freshly made up each time, sterilized by membrane filtration and administered from sterilized 1 ml disposable syringes (Gillette Scimitar). The metal lids of the glass jars were also sterilized in ultra-violet light for a minimum period of 30 min.

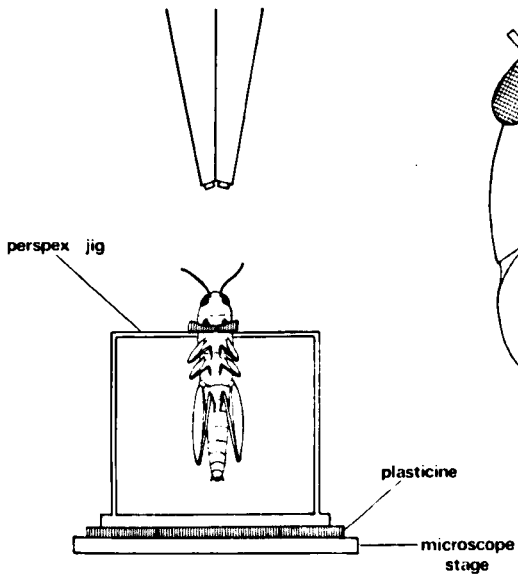
F. Surgical procedure

(i) Frontal approach

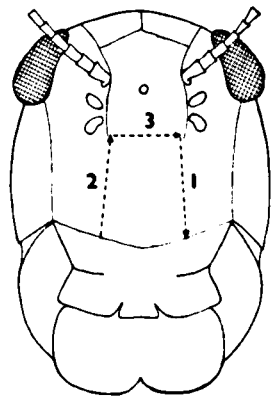
For operations in the vicinity of the frontal ganglion the LANGLEY (1962) and CLARKE and LANGLEY (1963 b) method of entry into the head capsule was adopted. Thus the anaesthetized insect was placed in a perspex jig with the frons, previously wiped clean, pointing upwards. The jig was transferred to the stage of a binocular microscope and held in place by plasticine (Diagram IIa). Illumination was provided by two high intensity lamps to which were fitted polaroid heat filters. Cuts 1-3 (Diagram IIb) were made in the frons and the U-shaped flap of cuticle and hypodermis so formed turned down ventrally to reveal three large frontal air sacs. These were carefully removed to expose the frontal ganglion and its associated nerves lying on top of the pharynx (Diagram IIc). Sterile ringer solution was immediately dispensed into the wound; its effect was to cause the frontal ganglion to lift slightly from the surface of the gut, thus facilitating detection of the fine pharyngeal nerves which connect the ganglion to the gut surface.

The frontal connectives, recurrent nerve and pharyngeal nerves were severed in two places and the middle portion removed to minimize the chances of the two cut ends rejoining.

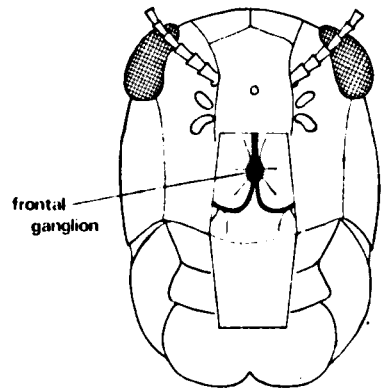
DIAGRAM II



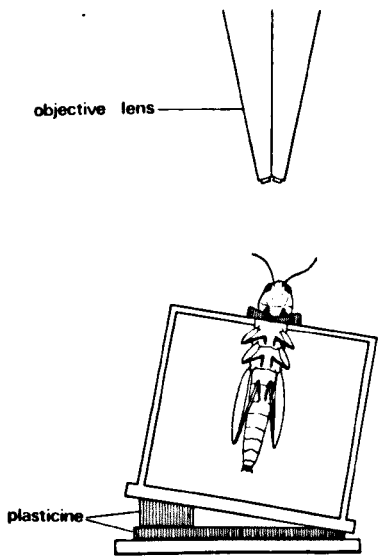
a



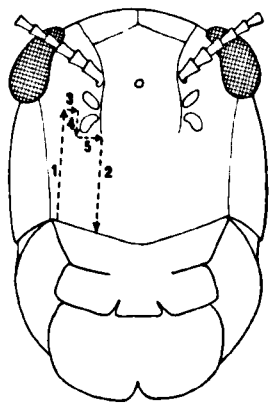
b



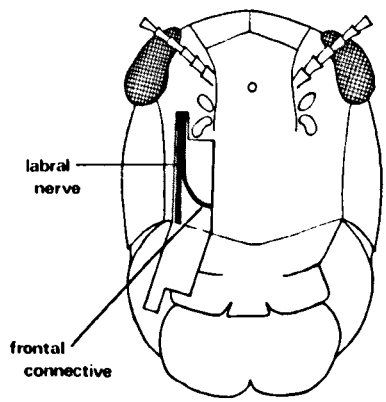
c



d



e



f

Removal of the frontal ganglion was accomplished by carefully severing all its attendant nerves and then simply picking it up from the surrounding fluid. Upon completion of the operation the flap was replaced into position and the wound left to heal without the addition of any sealing materials.

(ii) Front-lateral approach

A fronto-lateral method of approach into the head capsule was adopted during the performance of operations involving severance of the labral nerve or that part of the frontal connective which runs alongside it. The insect was fixed into the perspex jig, transferred to the microscope stage and the fronto-lateral region of the frons brought into the field of focus by propping up one end of the jig with a piece of plasticine (Diagram IId). Cuts 1-5 (Diagram IIe) were then made, the light brown oval patch of cuticle, which marks the point of origin of various head muscles, being carefully avoided. The flap of cuticle and hypodermis was turned down ventrally and sterile ringer solution immediately added to the preparation. The labral nerve and frontal connective could then be seen running close and parallel to one another (Diagram IIf). They can be distinguished on three counts: (1) the frontal connective lies inside the labral nerve; (2) it is thinner than the labral nerve; (3) a large trachea

frequently runs along the length of the frontal connective but never along the labral nerve. The appropriate nerve(s) was severed in two places, the middle portion removed and the flap of cuticle replaced.

The same cuts were made in controls as in operated animals. Sterile ringer solution was added to the preparation after the flap of cuticle had been turned back. The air sacs were removed (in the frontal approach), the appropriate nerve(s) or ganglion touched with fine forceps and the flap then replaced.

G. Post-operative treatment

Each operated animal was placed in a screw-cap glass jar (described previously) which in turn was transferred to a dust-proof cabinet at room temperature (about 21°C). This kept the animals relatively inactive until the wound had had time to heal (CLARKE and LANGLEY, 1963 b). The locusts remained unfed on the day of the operation (Day 1) but received grass the following day (Day 2). On Day 3, 48 hr after the operation, the animals were returned to the insectary and providing the procedures outlined above had been strictly adhered to it was possible to achieve 100% recovery from the operation.

H. Post-mortem examinations

Every insect that died or was sacrificed during the course of an experiment was subjected to a post-mortem examination. This was made to ensure that the appropriate nerves had been cut successfully (or ganglion removed) and that the cut ends had not rejoined. In cases of reconnection, or where some doubt existed, then the insect was excluded from the experimental data. Notes were made on the state of the animal at the time of death, e.g. formation of a second cuticle, gut contents, etc.

I. Measurement of growth

Changes in wet weight offer little indication of growth rate since they take into account neither variation in the amount of food in the gut nor variation in body water content from one individual to another. However, when information on day to day changes in the growth rate of an individual is required one has no choice but to use wet weight measurements and accept that they provide a rough guide only. Studies on the growth of insects have emphasised that during an instar their linear dimensions and hence their volume remain constant, while their wet weight approximately doubles (CLARKE, 1956). Throughout this study, therefore, a twofold increase in wet

weight has been taken to represent true growth, allowing as it does for individual variation in gut content and body water content. Two other types of growth, 'reduced growth' and 'little or no growth at all', are recognised from wet weight measurements; these are defined in Section II of Chapter III.

The locusts were weighed on a torsion balance at 24 hr intervals and immediately before feeding so as to reduce short-term fluctuations in weight caused by individual variation in gut contents.

J. Vital staining with methylene blue

Newly moulted fifth instar nymphs were starved for several days and then injected with a reduced (leuco) solution of methylene blue according to the method of STARK et al. (1969) (after PANTIN, 1946).

0.15 ml of the reduced dye was injected into the head capsule through the dorsal neck membrane. After 1 hr the injected insect was decapitated, the head pinned out in a wax dish and a small window cut in the frons cuticle. The preparation was flooded with cold 8% ammonium molybdate and left for 24 hr at 0°C. The required portion of the anterior stomatogastric nervous system was then dissected out, washed

in distilled water, dehydrated, cleared and mounted. (A schedule of the procedure employed is presented in the Appendix.)

K. Electron microscopy

Animals were killed by decapitation and the head pinned out in a wax dish. A window was cut in the frons and the preparation flooded with ice-cold 2.5% glutaraldehyde in 0.1 M phosphate buffer, pH 7.4, containing 0.17 M sucrose. The tissues were fixed for 2 hr at 0°C and then washed overnight at 0°C in 0.1 M phosphate buffer, pH 7.4, containing 0.34 M sucrose. It was at this stage that the necessary tissues were dissected out and transferred to fresh buffer. The tissues were post-fixed at 0°C in 1% OsO_4 in 0.1 M phosphate buffer, pH 7.4, containing 0.34 M sucrose. Then followed another washing in buffer, dehydration in a graded series of ethanols, pre-staining in uranyl acetate and finally embedding in Araldite resin. (A schedule of the procedure employed is provided in the Appendix.)

Silver or gold sections were cut with a glass knife on a Servall Porter-Blum MT-2 ultramicrotome, expanded with trichloro-ethylene vapour and mounted on coated grids (200-mesh). Sections were post-stained with Reynold's lead citrate (REYNOLDS, 1963) and examined under an AEI EM6B electron microscope.

L. Radiography

The technique of contact radiography was first applied to ecdysis by CLARKE (1956) who used a standard clinical Watson 'Mobilix' X-ray machine and high contrast X-ray film. This same machine was used during the present study and gave good, reproducible results.

A high contrast X-ray film (Ilford Industrial G) was enclosed within a lead-backed, light-proof holder held at a distance of 75 cm from the lens. The locust to be X-rayed was laid on one side and held in position against the film holder by means of sellotape applied across its legs. Alternatively, the subject was X-rayed in a side-on position while clinging to muslin wrapped tightly round a narrow stick placed adjacent to the film holder. A standard exposure time of 0.2 sec at 43 kV and 60 mA was used throughout with the diaphragm fully open. The film was developed for 6 min in a high contrast X-ray developer (Ilford PQX-1) and fixed for 10 min in F 52 fixer.

M. Presentation and analysis of data

The raw data for the work presented in this thesis is recorded in tabular form in the Appendix. Each animal in a particular experiment is allotted a number and the numbers quoted in the text correspond to those in the Appendix. Abbreviations used in the text, in tables or in the Appendix are listed and defined at the beginning of the Appendix.

In view of the wide disparity between the initial weights of newly moulted locusts, particularly adults, body weight is

expressed as a percentage of that at the time of the operation. For graphical purposes the operation weight equals 100% and for tabular purposes it equals 0%.

Statistical analysis, where applied, took the form of STUDENT's 't' test, the values of the probability 'P' being obtained from "Statistical Tables for Biological, Agricultural and Medical Research" (FISHER and YATES, 1953). The 5% level of significance (P = 0.05) was adopted.

CHAPTER III

RESULTS

SECTION I

SURGICAL INTERFERENCE WITH THE ANTERIOR STOMATOGASTRIC NERVOUS SYSTEM IN FLEDGLING *Locusta*: ITS EFFECT UPON SOMATIC GROWTH

After the final ecdysis the locust undergoes a period of somatic growth during which protein, lipid and carbohydrate accumulate in the fat body and proteins collect in the haemolymph. Growth of the cuticle and flight muscles is especially noticeable at this time (HILL *et al.*, 1968). The somatic growth period continues until a maximum body weight, the 'basic weight' (NORRIS, 1954) is attained. In both *Locusta* (PHIPPS, 1950; STRONG, 1966, 1968) and *Schistocerca gregaria* (HILL *et al.*, 1968) the basic weight is reached approximately ten days after final ecdysis. In female locusts ovarian growth only occurs when materials become available after somatic growth has finished (HILL *et al.*, 1968).

Surgical interference with the anterior stomatogastric nervous system was first performed on newly moulted adults, the large size of the head capsule facilitating the various operations. Animals of both sexes were employed in this study. They were weighed daily up until Day 10 post-operative

by which time the control males had virtually attained a basic weight. All weight changes are recorded in Table I of the Appendix.

The experimental treatments were as follows: operated controls; one frontal connective cut; anterior, median and posterior pharyngeal nerves cut; recurrent nerve cut; both frontal connectives cut; recurrent nerve plus both frontal connectives cut; frontal ganglion removed. These treatments comprised three separate experiments, and since no differences were observed between the control groups for the three experiments the results are combined. Operative technique and post-operative care followed the pattern set out in Chapter II. For identification purposes each animal was marked with cellulose dope in the region of the pronotum. Unless otherwise stated, the graphs indicate the mean daily weight changes of those animals surviving to Day 10, with the operation weight equalling 100%.

One frontal connective cut (6 m, 6 f)

It can be seen from Fig. 1 that the cutting of one frontal connective had no adverse effect upon somatic growth when compared to the controls.

Anterior, median and posterior pharyngeal nerves cut (5 m, 7 f)

The anterior and posterior pharyngeal nerves have been described in Locusta by CLARKE and LANGLEY (1963b). According to ROOME (1968) a pair of median pharyngeal nerves leave the frontal ganglion, between the anterior and posterior pairs, and branch to the dorsal dilator muscles of the pharynx and

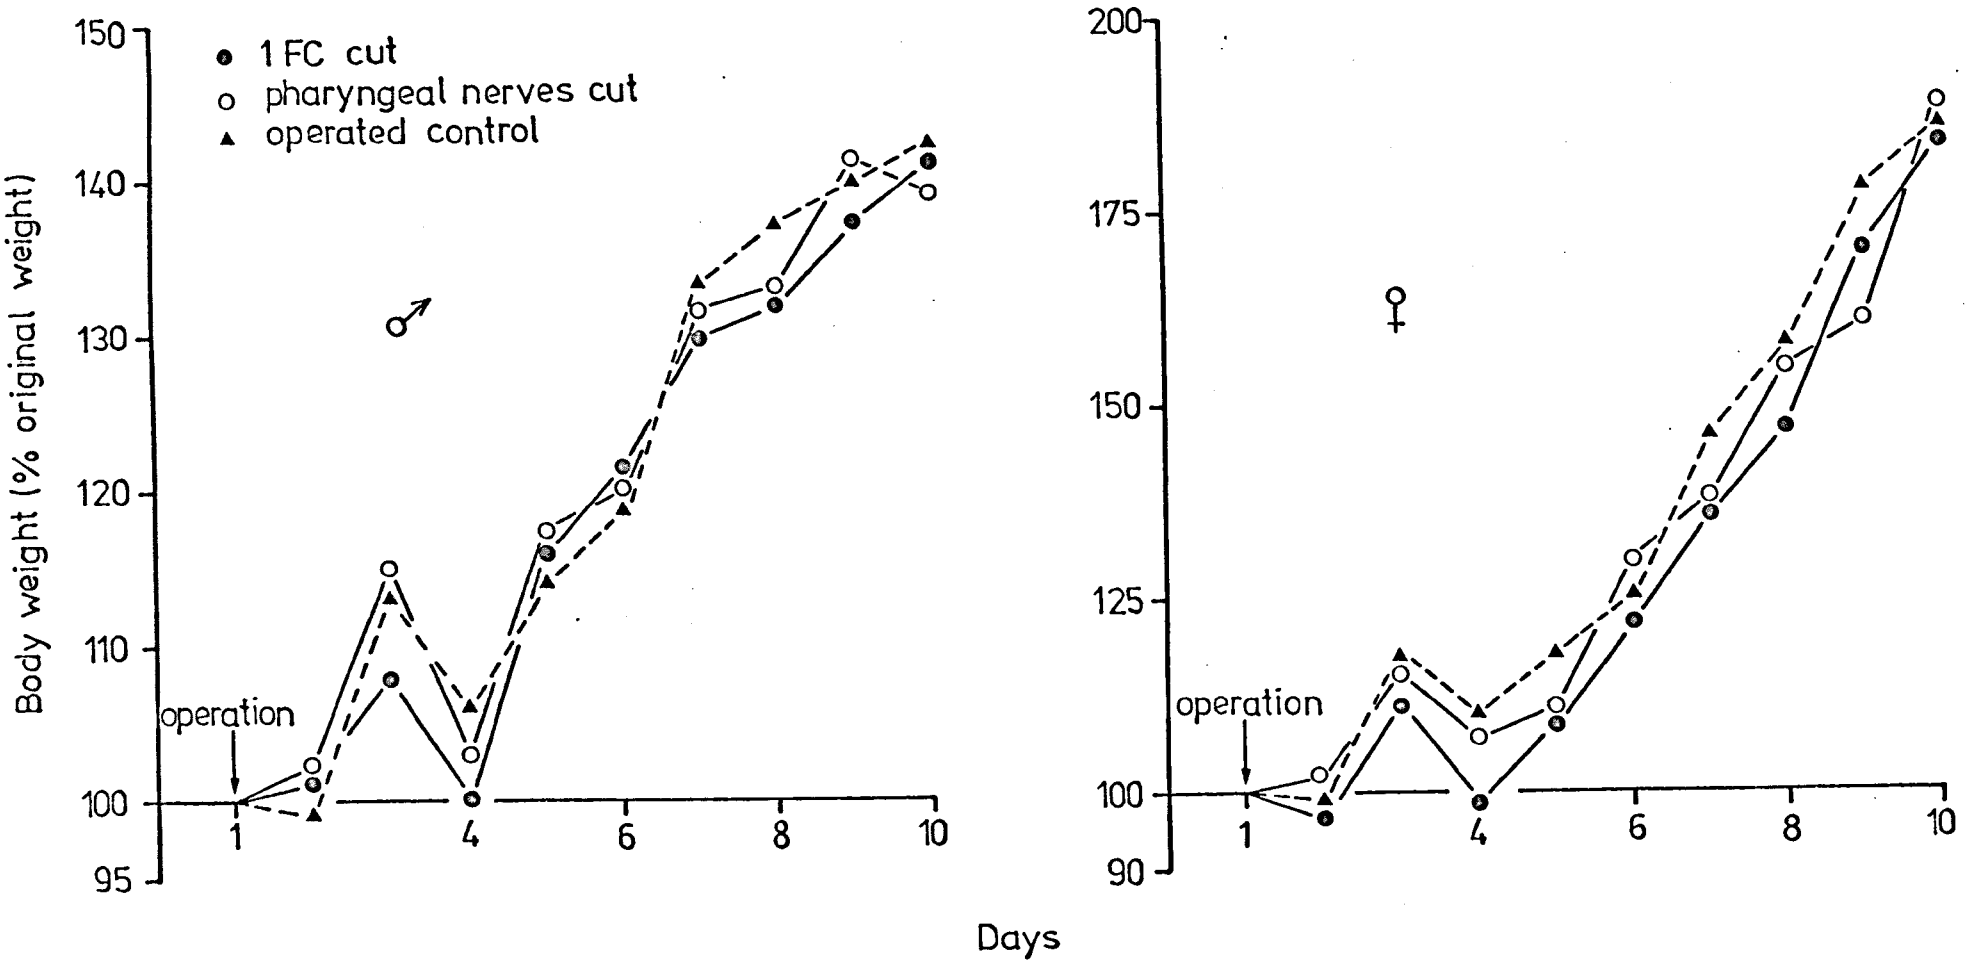


FIG 1. Growth after severance of one frontal connective, and after severance of anterior, median and posterior pharyngeal nerves.

to the muscular coat of the pharynx. The morphology of these nerves is considered in Section IV.

Somatic growth was unaffected by severance of the anterior, median and posterior pharyngeal nerves, the growth curves of the operated animals being no different from those of the controls (Fig. 1).

Recurrent nerve cut (6 m, 8 f)

The cutting of the recurrent nerve led to a reduced growth rate among the operated animals when compared to the controls (Fig. 2).

In the blowfly, Phormia regina (DETHIER and BODENSTEIN, 1958; DETHIER and GELPERIN, 1967) and in adult male Schistocerca (FRASER ROWELL, 1963) the operation induces hyperphagia, which may also be its effect in adult Gryllus bimaculatus (ROUSSEL, 1966). Recurrent nerve severance inhibits crop emptying in adult Melanoplus differentialis (DOGRA and EWEN, 1971) and also in Leucophaea maderae (SCHARRER, 1945; ENGELMANN, 1968; TAYLOR, 1969).

Both frontal connectives cut (14 m, 15 f)

The 21 operated animals surviving to Day 10 can be divided into two groups: those maintaining a constant weight (14), and those showing fairly considerable weight increases (7) which, in the majority of cases, are lower than those of the controls (Fig. 3).

In young adult Gryllus the cutting of both frontal connectives brings about a rapid early death (ROUSSEL, 1966), while in adult female Melanoplus the operation inhibits crop emptying (DOGRA and EWEN, 1971).

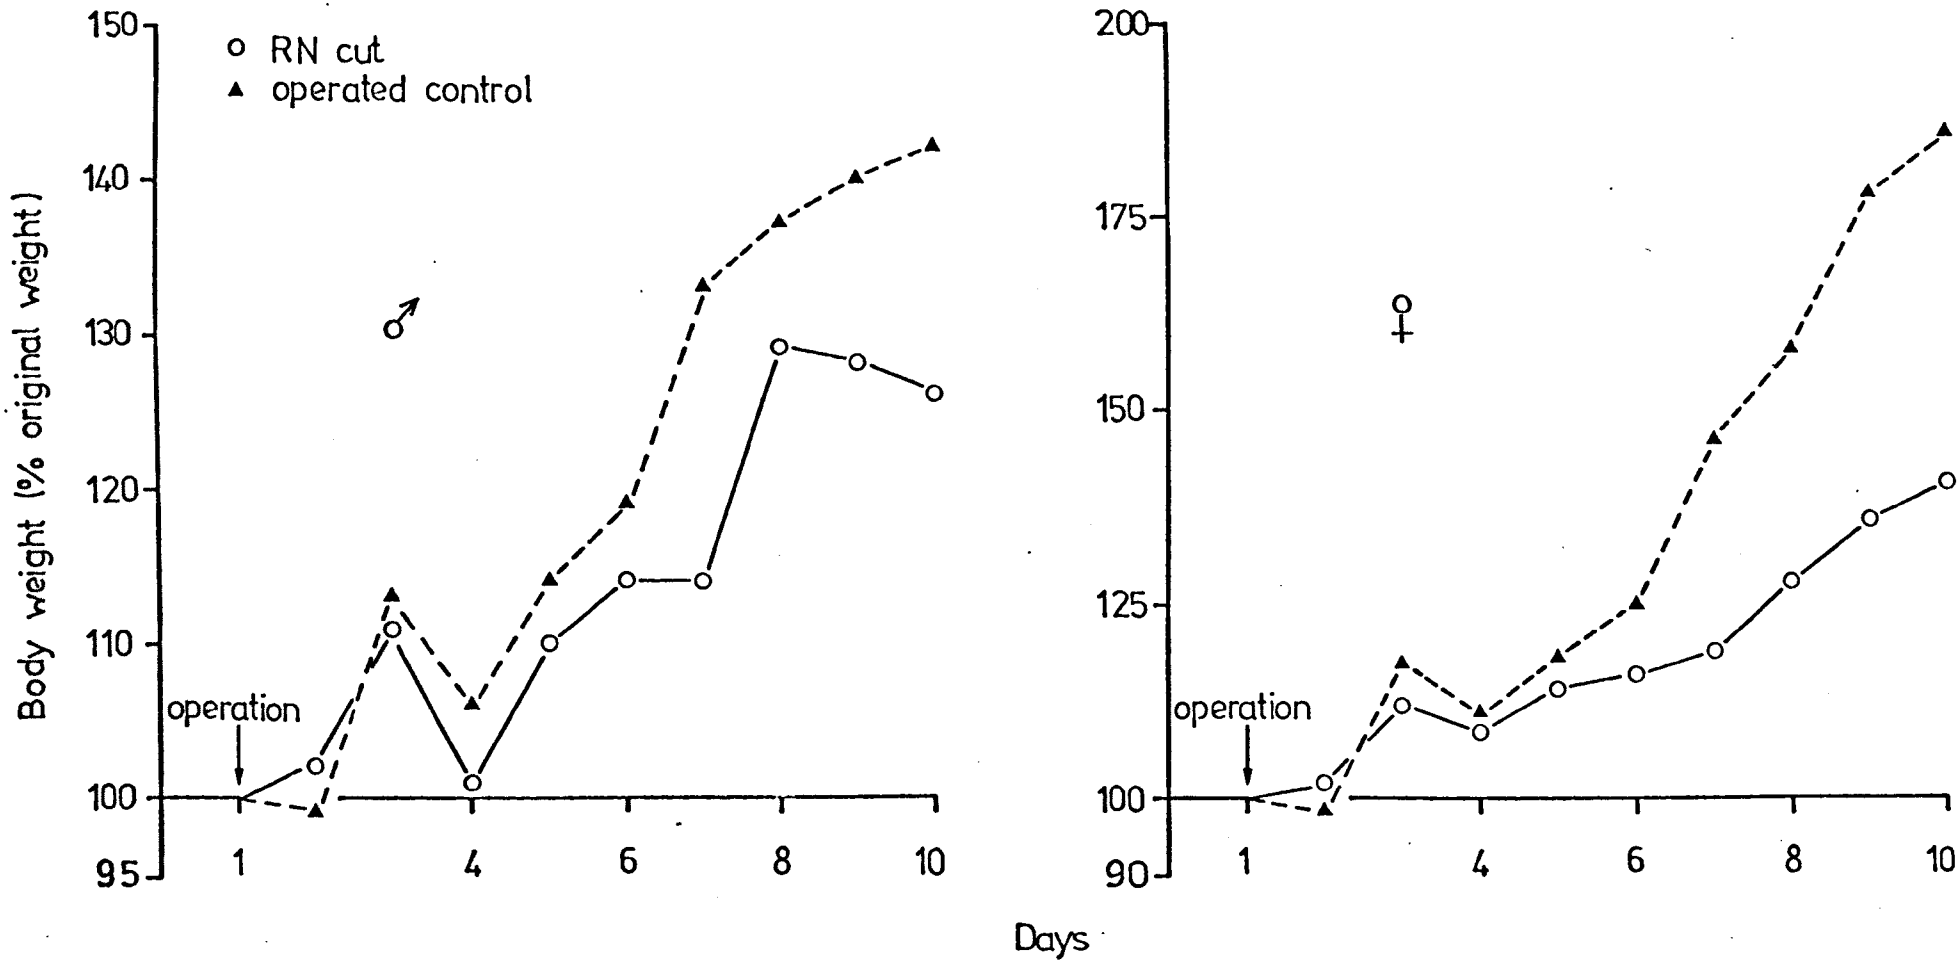

Fig 2. Growth after severance of the recurrent nerve.

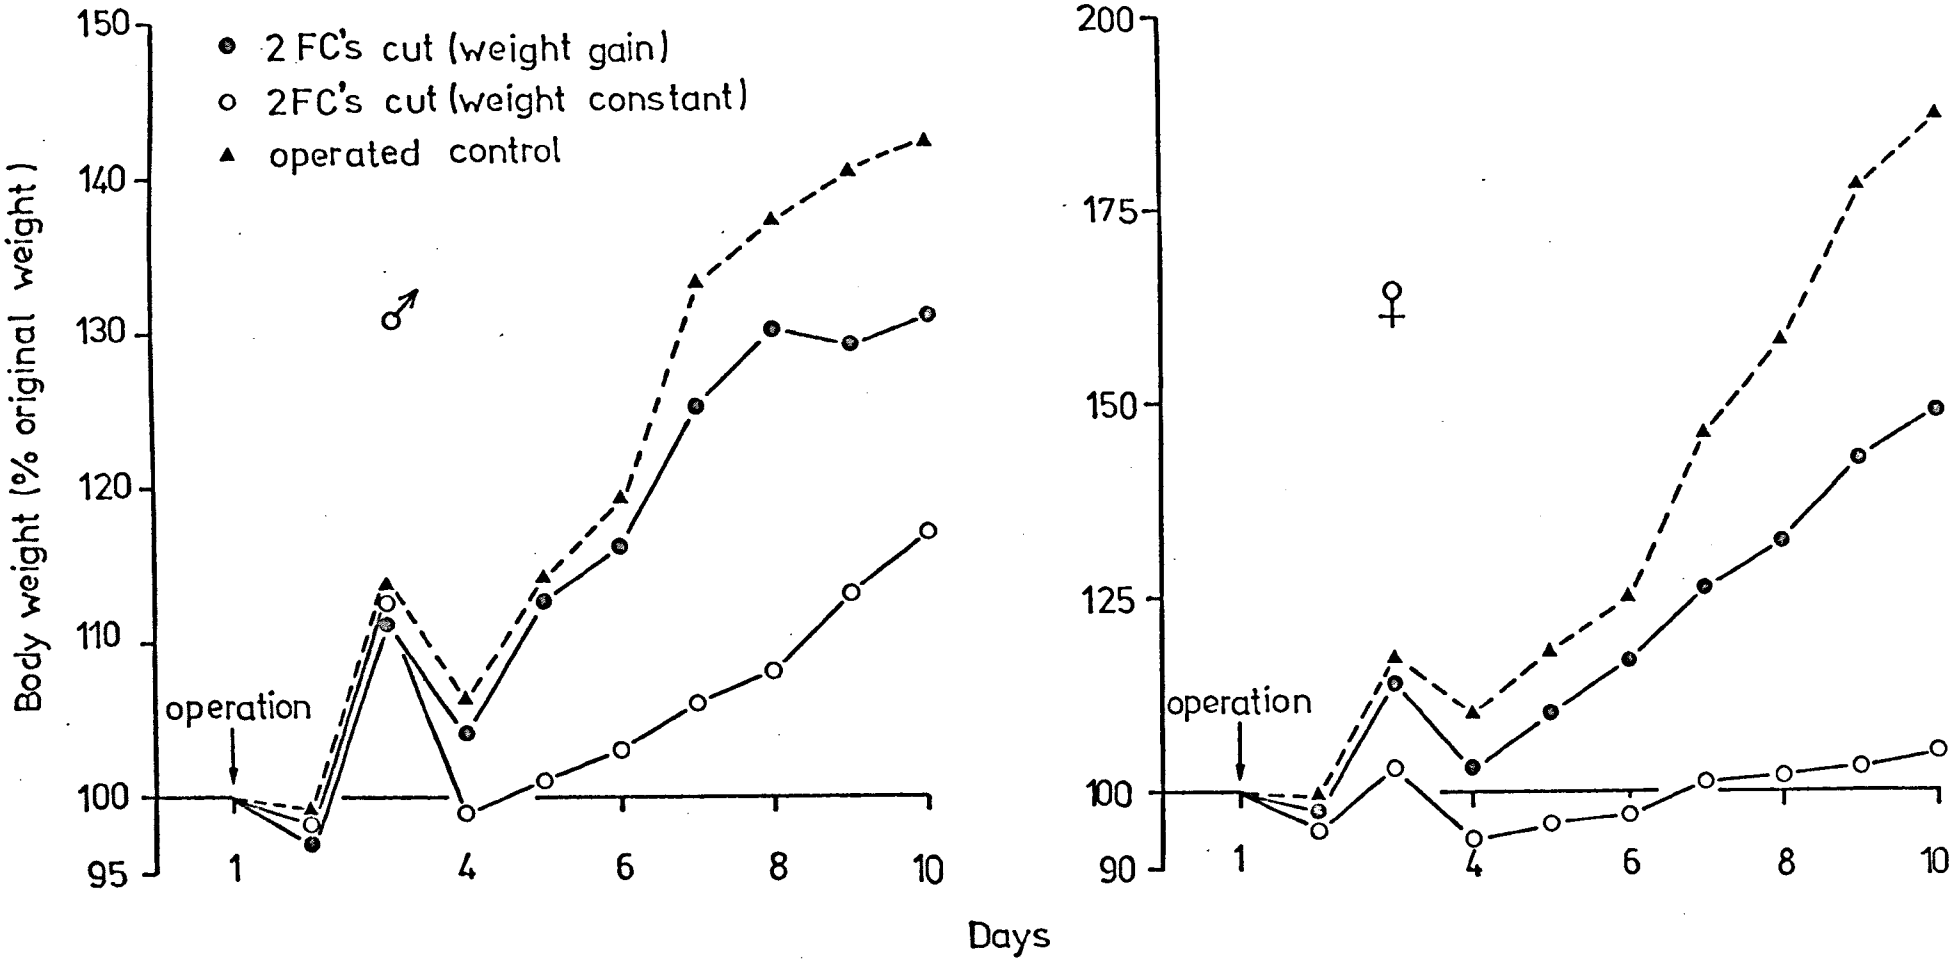

FIG 3. Growth after severance of both frontal connectives.

Recurrent nerve plus both frontal connectives cut (14 m, 15 f)

The operation was attended by an early high mortality with only 8 animals surviving to Day 10. 3 of these maintained a constant weight throughout the experimental period and the remaining 5 exhibited fairly considerable weight increases which were, however, lower than those of the controls (Fig. 4).

Removal of the frontal ganglion (22 m, 24 f)

Mortality was also high after frontal ganglionectomy, 34 operated animals dying before Day 10. The vast majority of these animals died at weights which were lower than those recorded at the time of the operation. The 12 animals surviving to Day 10 can be divided into three groups (Fig. 5): those losing weight (5 animals); those maintaining a constant weight (6 animals); and those showing fairly considerable weight increases (1 animal).

Adult Locusta (CLARKE and LANGLEY, 1963; STRONG, 1966), adult Schistocerca (HILL et al., 1966) and adult Melanoplus (GILLOTT et al., 1970) maintain a constant weight after frontal ganglionectomy. Immature adult Gryllus (ROUSSEL, 1966) either maintain a constant weight or lose weight after the operation, but survive for a limited period only. Frontal ganglionectomy in adults of the beetle Necrophorus vespillo, on the other hand, has no effect upon growth (ROUSSEL, 1966). The majority of workers (HIGHNAM et al., 1966; ROUSSEL, 1966; GILLOTT et al., 1970; DOGRA and EWEN, 1971) conclude that the operation interferes with crop emptying, causing food to accumulate in the foregut.

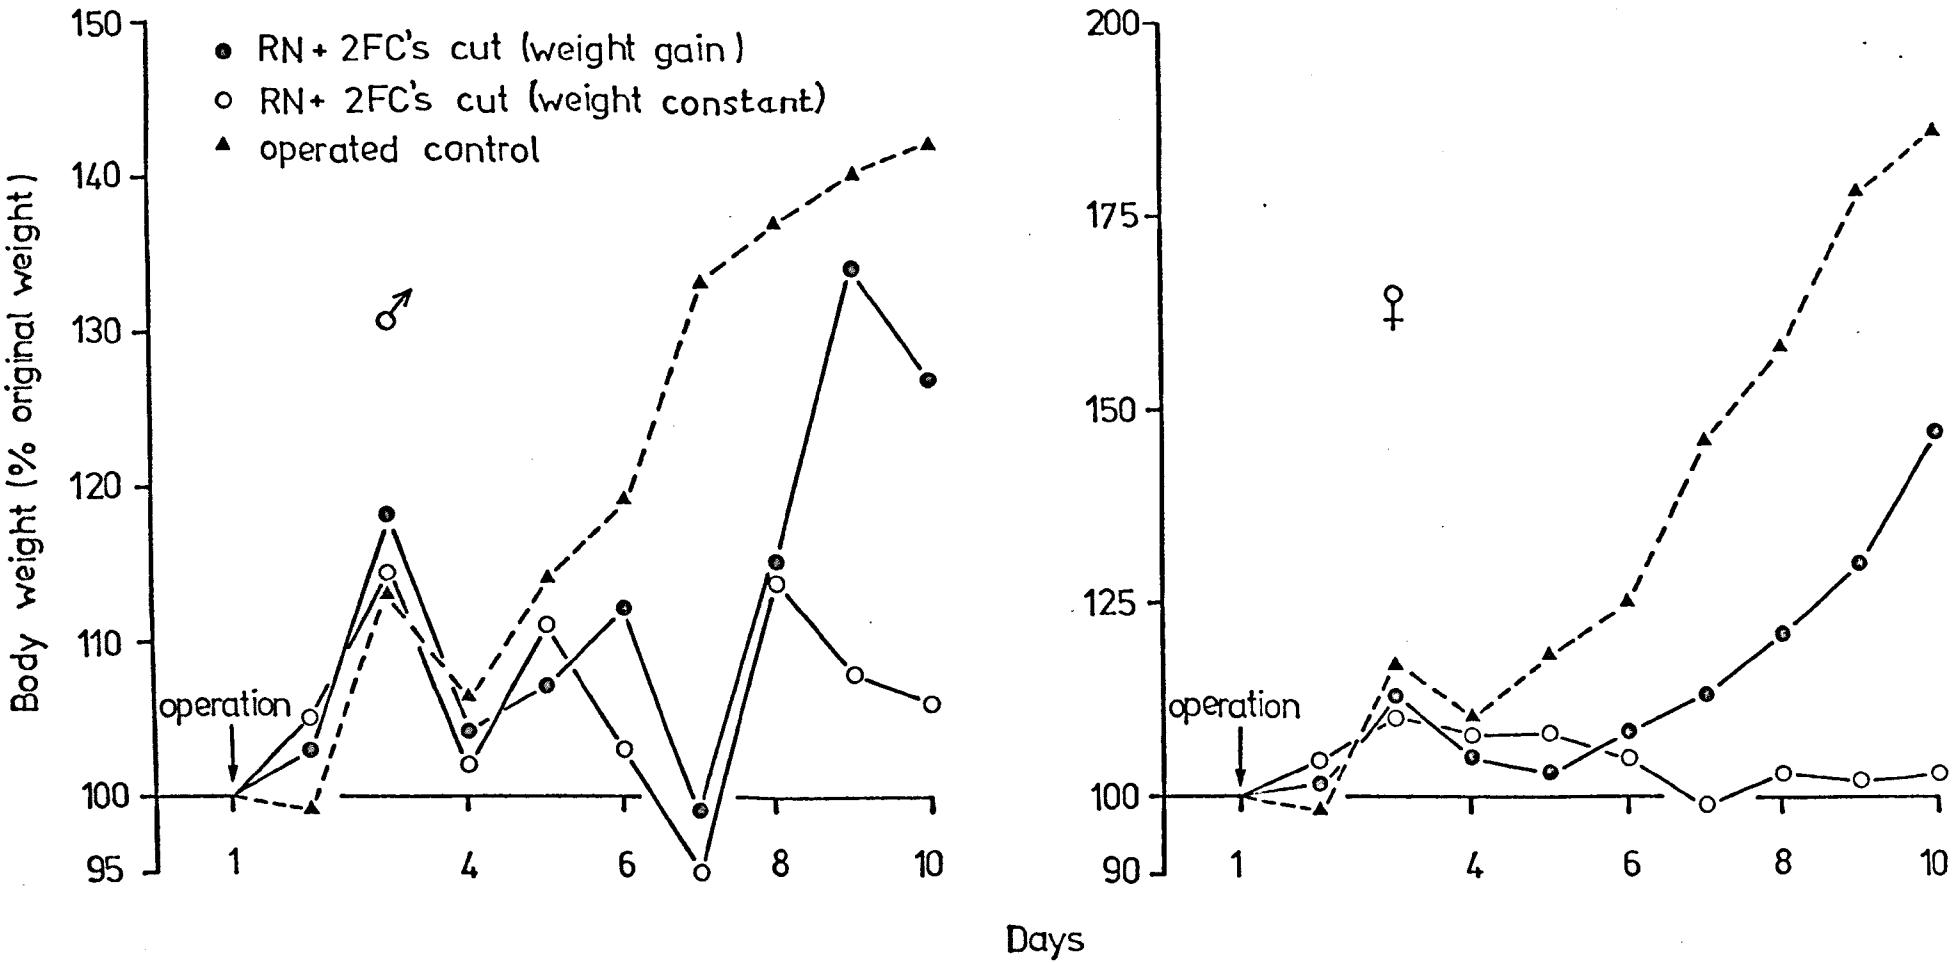

FIG 4. Growth after severance of recurrent nerve plus both frontal connectives.

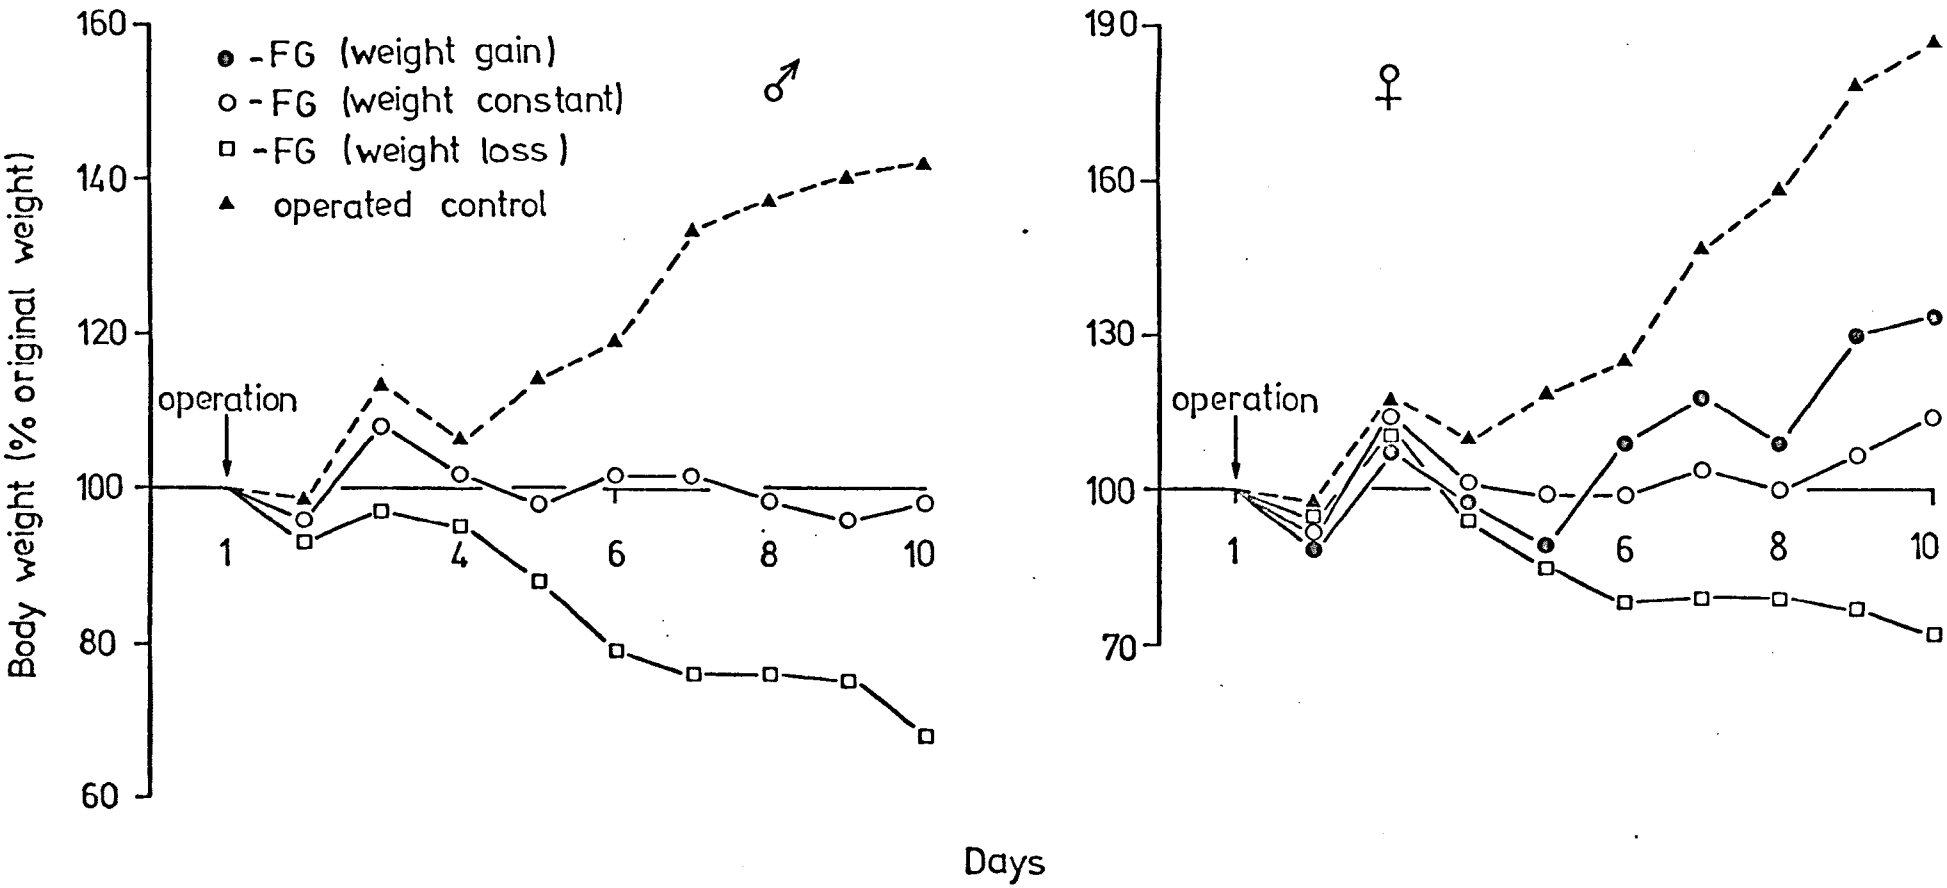

FIG 5. Growth after removal of the frontal ganglion.

It is clear that the separation of the frontal ganglion from the surface of the foregut is not a growth arresting operation when performed in adult animals. Neither does the severance of both frontal connectives, or the severance of the recurrent nerve plus both frontal connectives block growth in every operated animal. The results of the latter operation suggest that alternative nervous pathways to those outlined by CLARKE and LANGLEY (1963c, d) are relaying sensory information from the foregut to the brain and corpora cardiaca. One possibility is the hypocerebral ganglion ⟶ NCC I route of STRONG (1966).

The effect on growth of surgical interference into the anterior stomatogastric nervous system is considered further in Section II, where the majority of the above operations are performed on newly moulted fifth instar nymphs.

SECTION II

SURGICAL INTERFERENCE WITH THE ANTERIOR STOMATOGASTRIC NERVOUS SYSTEM IN FIFTH INSTAR *Locusta*: ITS EFFECT UPON GROWTH AND MOULTING

JOUSSET DE BELLESME (1877) was the first to implicate air in the process of ecdysis. He showed that the pronounced enlargement of freshly emerged dragon-flies was accomplished by internal air pressure built up, not in the main tracheae, but in the digestive tract. Similar observations have since been made in many insect species, including the two acridids, *Stauronotus maroccanus* (KUNKEL D'HERCULAIS, 1890) and *Locusta migratoria* (DUARTE, 1939).

Although TESTENOIRE and LEVRAT were using X-rays in the field of insect investigation as long ago as 1896, sixty years were to elapse before the technique was first applied to ecdysis. CLARKE (1956) found that the locust, with its thick body, was an ideal subject for the differential absorption of X-rays, and from radiographs obtained he was able to determine the function of the dorsal abdominal air sacs during ecdysis and subsequent instar development. The same radiographic technique is used in the present investigation to determine the effect of various surgical interruptions into the anterior stomatogastric nervous system on the processes of gut emptying and air swallowing at ecdysis. The radiographs of operated animals presented in the text depict the maximum amounts of air that could be observed in the gut during attempted ecdysis.

The effect of these surgical interruptions on growth is measured as daily change in body weight, and the weight measurements of all operated animals are recorded in Tables II to IX of the Appendix. Three types of growth are recognized:

(i) True growth - a twofold or more increase in the operation weight. Control animals fit into this category, and the mean maximum percentage weight increases of operated and control animals exhibiting true growth are compared for each operation.

(ii) Reduced growth - 50 to 100% increase in the operation weight.

(iii) Little or no growth - 0 to 50% increase in the operation weight.

Newly moulted animals of both sexes were employed in this study. The techniques of microsurgery and radiography, together with the methods of sampling experimental insects, have been described in Chapter II. Unless otherwise stated the growth curves in Figs. 6 to 13 are for those animals moulting (or attempting to moult) on the day by which 50% of the operated population have undergone ecdysis (or attempted ecdysis). In Tables 2 to 9 the operation weight equals 0%, while in Figs. 6 to 13 it equals 100%.

Experiment 1

X-ray analysis of operated control fifth instar locusts over a period covering the final moult

Four operated control fifth instar nymphs were X-rayed at regular intervals from the time feeding ceased prior to ecdysis until two days after the final moult when feeding was well under way again. A selected sequence of radiographs taken from one particular individual is presented as Plates 1-24. In a recent paper VINCENT (1971) conveys a time scale, based on casual observation, of superficial changes taking place during the final ecdysis in Locusta. This was found to correspond reasonably well with the scale of external changes observed in animals of the present experiment.

(Note: The X-ray machine was housed in a room whose ambient temperature was some 5°C below that of the insectary. The time sequence presented below may, therefore, represent a slight exaggeration of what happens under normal insectary conditions.)

Plates 1 and 2

The first bubble of air appears in the foregut 32 hr before ecdysis. Approximately 24 hr later the amount of air in the crop has increased but air is still absent from the hindgut. Digestion of the old endocuticle at this time makes the locust soft to touch.

Plates 3, 4 and 5

Air is first observed in the hindgut 4 hr before ecdysis. The amount increases during the next hour and 1 hr before moulting even more air is present in the hindgut.

Plate 6

30 min before ecdysis the locust alters its position on the perch to one where the head points downwards so that maximum use of gravity can be made during moulting. Longitudinal contractions of the abdomen at this time are very obvious as air continues to enter the hindgut.

Plates 7 and 8

The wing pads begin to separate 20 min before ecdysis and 4 min later they are fully apart. Separation of the wing pads is taken to represent the start of ecdysis (VINCENT, 1971). The foregut expands as more air is swallowed and air is visible in the midgut caeca. Flexing movements of the abdomen at this time are very intense.

Plates 9, 10, 11 and 12

The haemolymph pressure, which is already at an elevated level on account of the high blood volume of locusts at this time (LEE, 1961), is raised still further by the continued expansion of the foregut. The high blood pressure and the actively contracting body muscles together cause the old cuticle to split along predetermined ecdysial lines of weak-

ness situated in the mid-dorsal region of the thorax and along the epicranial suture of the head (DUARTE, 1939).

Plates 13 and 14

As the head and thorax emerge so the shed cuticle of the mouthparts becomes visible. The wings are withdrawn from the old wing pad cuticle and the gut reaches its maximum state of distension at this time. The limbs finally escape and the locust remains suspended from the old cuticle by the tip of the abdomen, for a period of 7 min, before falling to the ground. This rest period is most probably associated with preliminary hardening of the legs (VINCENT, 1971).

Plates 15, 16, 17 and 18

The newly emerged adult quickly regains the perch using only the front and middle pairs of legs which by this time are sufficiently hard for a firm grip to be applied. The gut remains distended with air thus enabling the blood to act as a hydrostatic skeleton and this, together with continuing muscular contractions in the region of the abdomen, facilitates expansion of the new cuticle and unfolding of the hypodermis to its fullest extent. Blood is forced into the wings which respond by gradually unfolding until they are completely expanded some 40 min after the moult. It is clear that some food has remained in the midgut during the moult. The midgut is the only region of the gut where food could be retained since the linings of both the foregut and hindgut are moulted.

Plate 19

The wings are folded up to their normal resting position once expansion is complete (1¼ hr after ecdysis) and as they harden so they become more difficult to visualise in the ensuing radiographs.

Plates 20, 21 and 22

The foregut has begun to collapse 2 hr after ecdysis and by the time 6 hr have elapsed it has assumed more normal dimensions. 12 hr after the moult the hindgut has expelled all but the last bubble of air. The fully expanded air sacs are now clearly visible. CLARKE (1956) states that the abdominal air sacs of the locust form a system permitting changes of volume at an ecdysis when the mass and density of the tissues remain constant. The air sacs are gradually obliterated by the developing tissues so that by the end of the stadium they have become completely occluded.

Plate 23

The first meal is taken 12-24 hr after ecdysis and food can be detected along the length of the gut at 24 hr. The S-bend of the colon, mentioned by ALBRECHT (1953) and figured in drawings from radiographs by GOODHUE (1963), is clearly visible.

PLATE 21. 6 hours after final escape from the old cuticle.

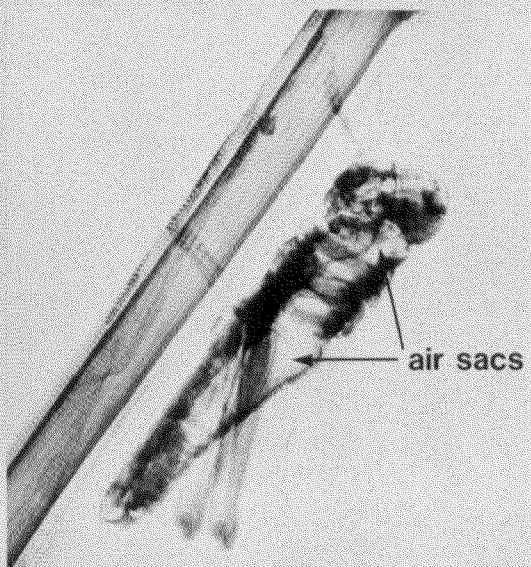
PLATE 22. 12 hours after final escape from the old cuticle.

PLATE 23. 24 hours after final escape from the old cuticle.

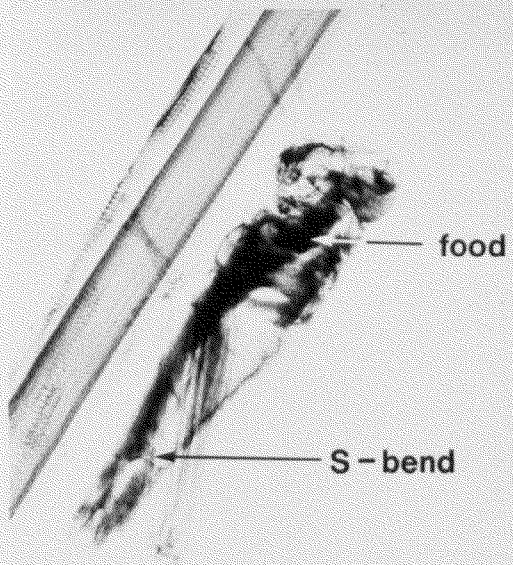
PLATE 24. 48 hours after final escape from the old cuticle.

PLATES 21–24

21



22



23

24

Plate 24

Even more food is present in the crop and midgut and the S-bend in the colon is again apparent. The adductor muscles of the mandibles are also very obvious.

Summary

Air is first detected in the foregut 32 hr before the moult. 28 hr later it appears in the hindgut. This sort of timing is to be expected since the foregut will be emptying and swallowing well before the hindgut has removed the last traces of food and begun to take in air through the anus. The gut reaches its maximum state of distension several minutes before final escape from the old cuticle is accomplished. Dilation is maintained for 1-2 hr after moulting, thus allowing unfolding of the hypodermis and expansion of the new cuticle to take place. By 12 hr after ecdysis the gut has assumed more normal dimensions and the first meal is taken 12-24 hr after the moult.

Experiment 2

The effect of cutting the recurrent nerve on growth and moulting

The experimental treatments were as follows:

(a) Recurrent nerve cut 14 animals

(b) Operated controls 8 animals

Results

Sectioning the recurrent nerve produced two quite distinct responses:

(i) 50% of the operated animals died before Day 10 and in every individual the foregut, midgut and most of the hindgut were packed full of undigested grass at autopsy (Table 1, Plate 25).

TABLE 1. Gut contents of response (i) operated animals at autopsy

Animal No.	Food content of gut				
	Crop	Midgut	Hindgut		
			Ileum	Colon	Rectum
1	+++++	+++++	+++++	++++	+
3	+++++	+++++	+++++	+++	+
4	+++++	+++++	+++++	+++	-
8	+++++	+++++	+++++	++	-
9	+++++	+++++	++++	+	-
11	+++++	+++++	+++++	+	-

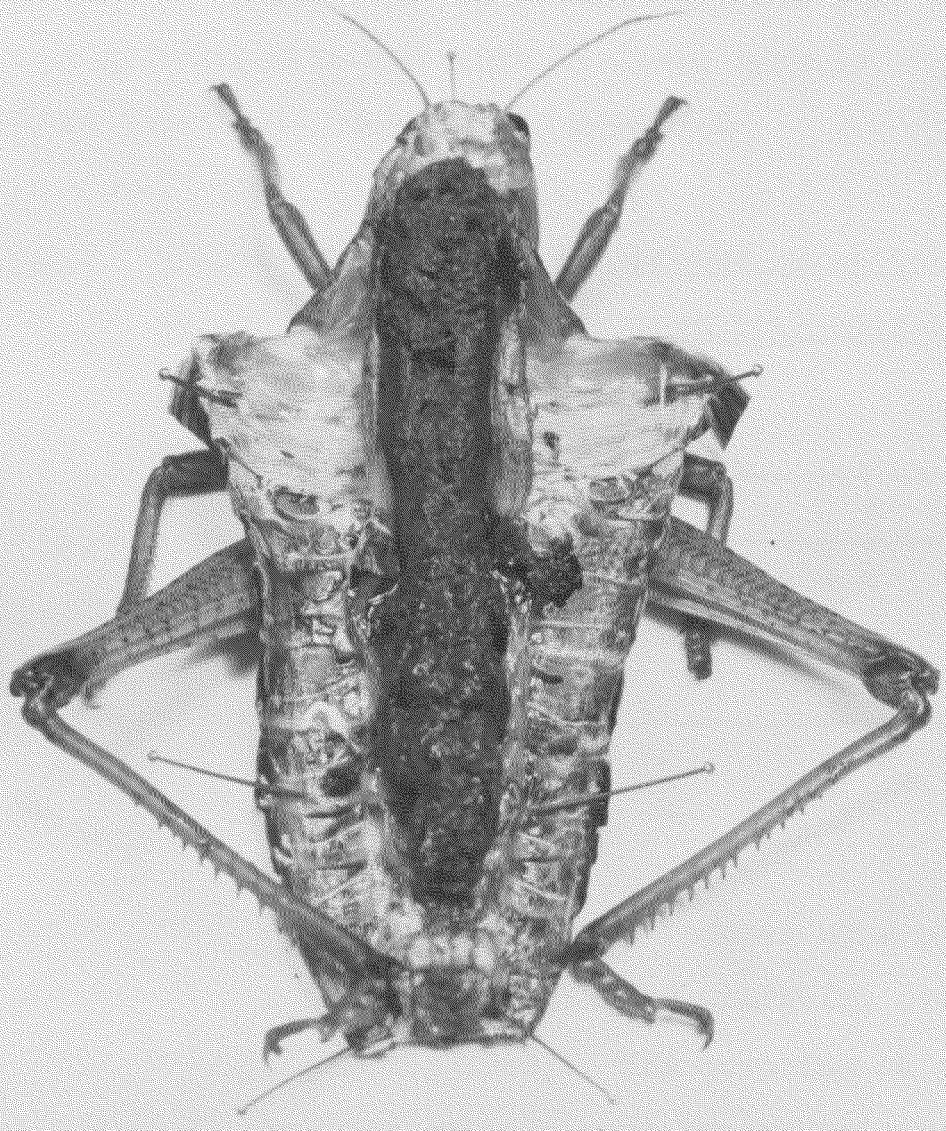
PLATE 25. Dorsal dissection of a recurrent nerve cut fifth instar locust dying before Day 10. Note the presence of vast quantities of food in the foregut, midgut and much of the hindgut.

PLATE 25



These animals did not produce any faeces and the midgut caeca were frequently shrunken in appearance and squashed against the body wall by the excessive amount of grass in the midgut.

(ii) The other 50% operated animals grew at a reduced rate compared to the controls and moulted to adults, on average one day later (Fig. 6). Table 2 shows that the mean maximum percentage weight gain of these animals was significantly lower than that of the controls.

TABLE 2. Comparison of the mean maximum percentage weight increases of response (ii) operated animals and the controls

Treatment	Individuals	Mean	S.E.	t	'P'
RN cut, response (ii)	7	145	4	6.00	0.001
Controls	8	175	3		

Conclusions

Recurrent nerve severance frequently induces hyperphagia (DETHIER and BODENSTEIN, 1958; DETHIER and GELPERIN, 1967; GELPERIN, 1967; FRASER ROWELL, 1963). The question as to whether response (i) operated animals were hyperphagic must remain open since they were not made the subject of any quantitative food measurements. Their gut condition is identical to that of adult Gryllus bimaculatus (ROUSSEL, 1966) after recurrent nerve severance. In both cases death

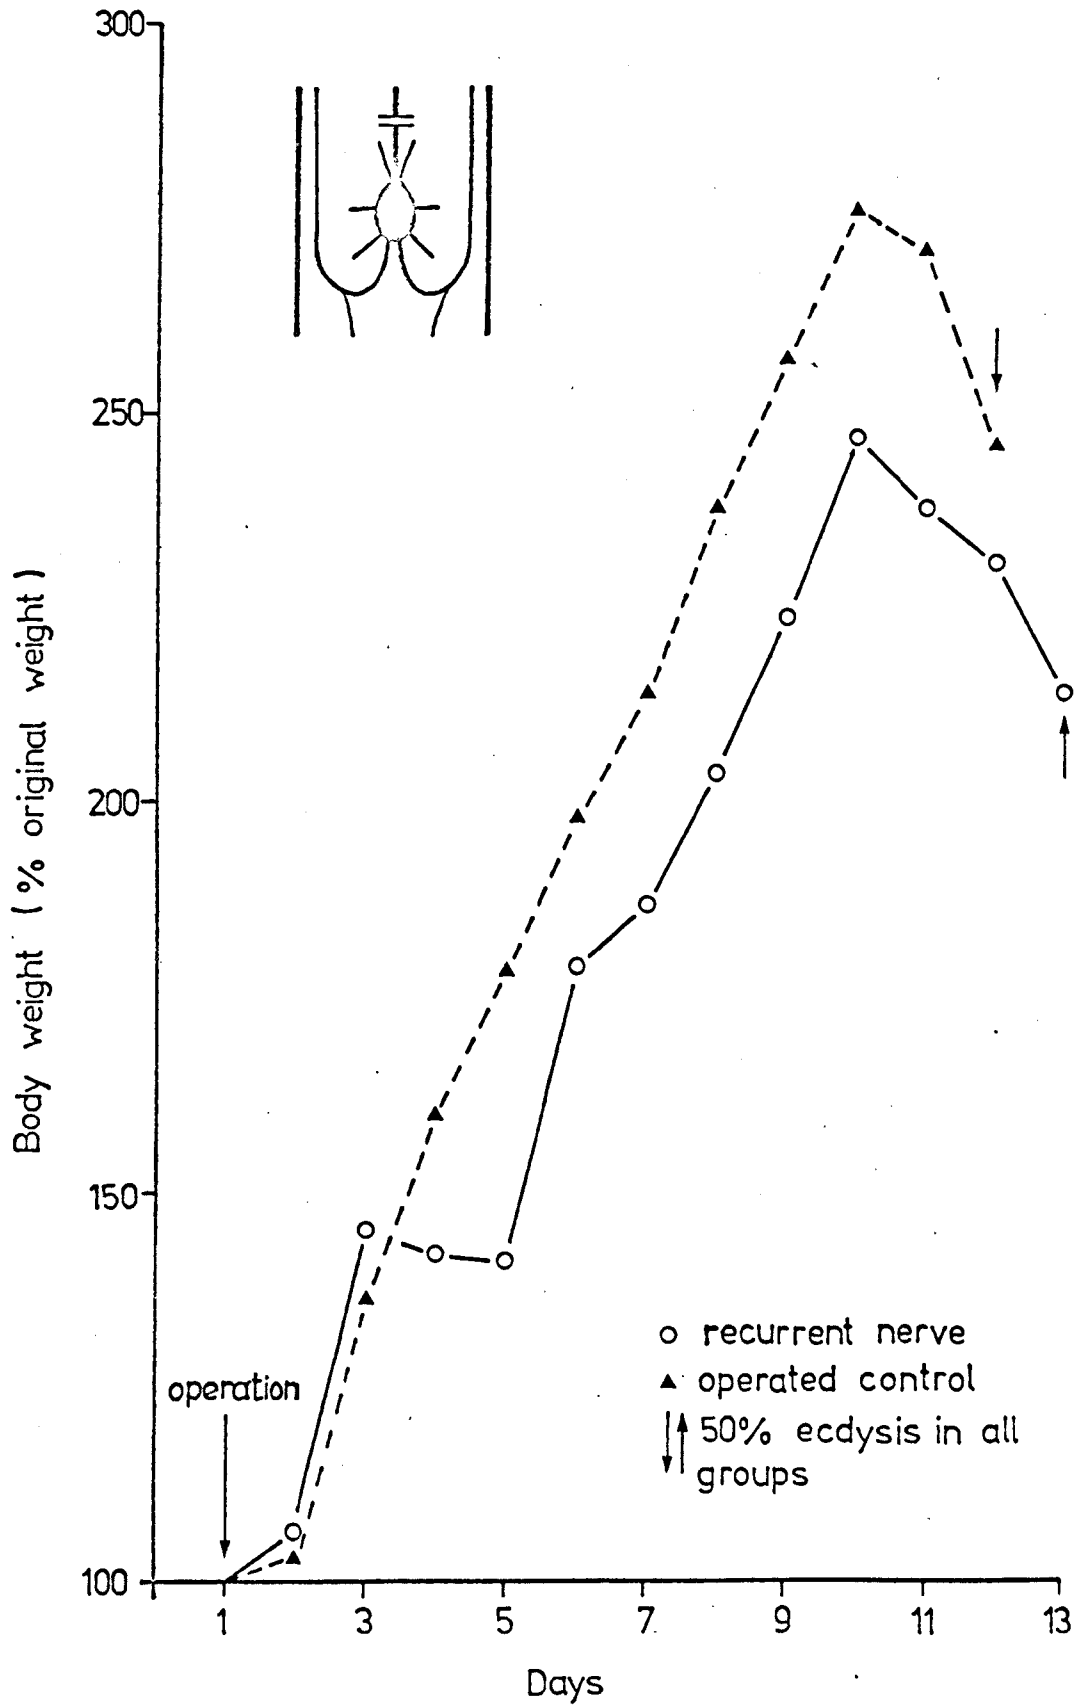


FIG 6. Growth after severance of recurrent nerve.

is ultimately due to lack of metabolites entering the haemolymph, the operation having an adverse effect upon the digestive mechanisms of these insects. The remaining (response (ii)) operated animals behave in a similar manner to the third instar nymphs of CLARKE and LANGLEY (1963b), growing at a reduced rate compared to the controls and showing a slight delay in moulting.

Experiment 3

The effect of cutting one frontal connective (proximal or distal to branches) on growth and moulting

ROOME (1968) makes brief mention of fine nerves leaving each frontal connective in fourth instar Locusta. Intra-vitam injection of methylene blue and subsequent dissection confirmed the existence of these nerves in fifth instars. The fine nerves, usually three in number, leave each frontal connective in the region where this nerve passes between the retractors of the mouth angle and the posterior retractors of the labrum. Sensory cell bodies, lying on the dorsal surface of the muscular coat of the pharynx, were seen to be associated with some of the fine nerve branches; motor nerve endings to some of the nerve branches were also apparent. The neuromorphology of this region of the stomatogastric nervous system is considered in more detail in Section IV. Suffice it to say here that sensory information from the pharynx can be relayed to the brain and/or corpora cardiaca via the fine nerve branches of the frontal connectives as

well as via the anterior and posterior pharyngeal nerves (LANGLEY, 1962; CLARKE and LANGLEY, 1963b, c).

The treatments in Experiment 3 were as follows:

(a) One frontal connective cut (proximal to branches) — 16 animals

(b) One frontal connective cut (distal to branches) — 14 animals

(c) Operated controls — 18 animals

Results

Animals of treatments (a) and (b) grew at a similar rate to the controls, with treatment (b) animals tending to moult on average one day later than those in the other two groups (Fig. 7). Table 3 shows that the mean maximum percentage weight increases of the operated and control groups were not significantly different. None of the operated animals leaked digestive fluid at any time during the experiment.

TABLE 3. Comparison of the mean maximum percentage weight increases of treatments (a), (b) and (c) animals.

Treatment	Individuals	Mean	S.E.		t	'P'
(a) 1 FC cut (proximal)	14	176	4	a:b	0.71	0.5-0.4
(b) 1 FC cut (distal)	12	172	4	a:c	1.00	0.4-0.3
(c) Control	16	171	3	b:c	0.20	0.9-0.8

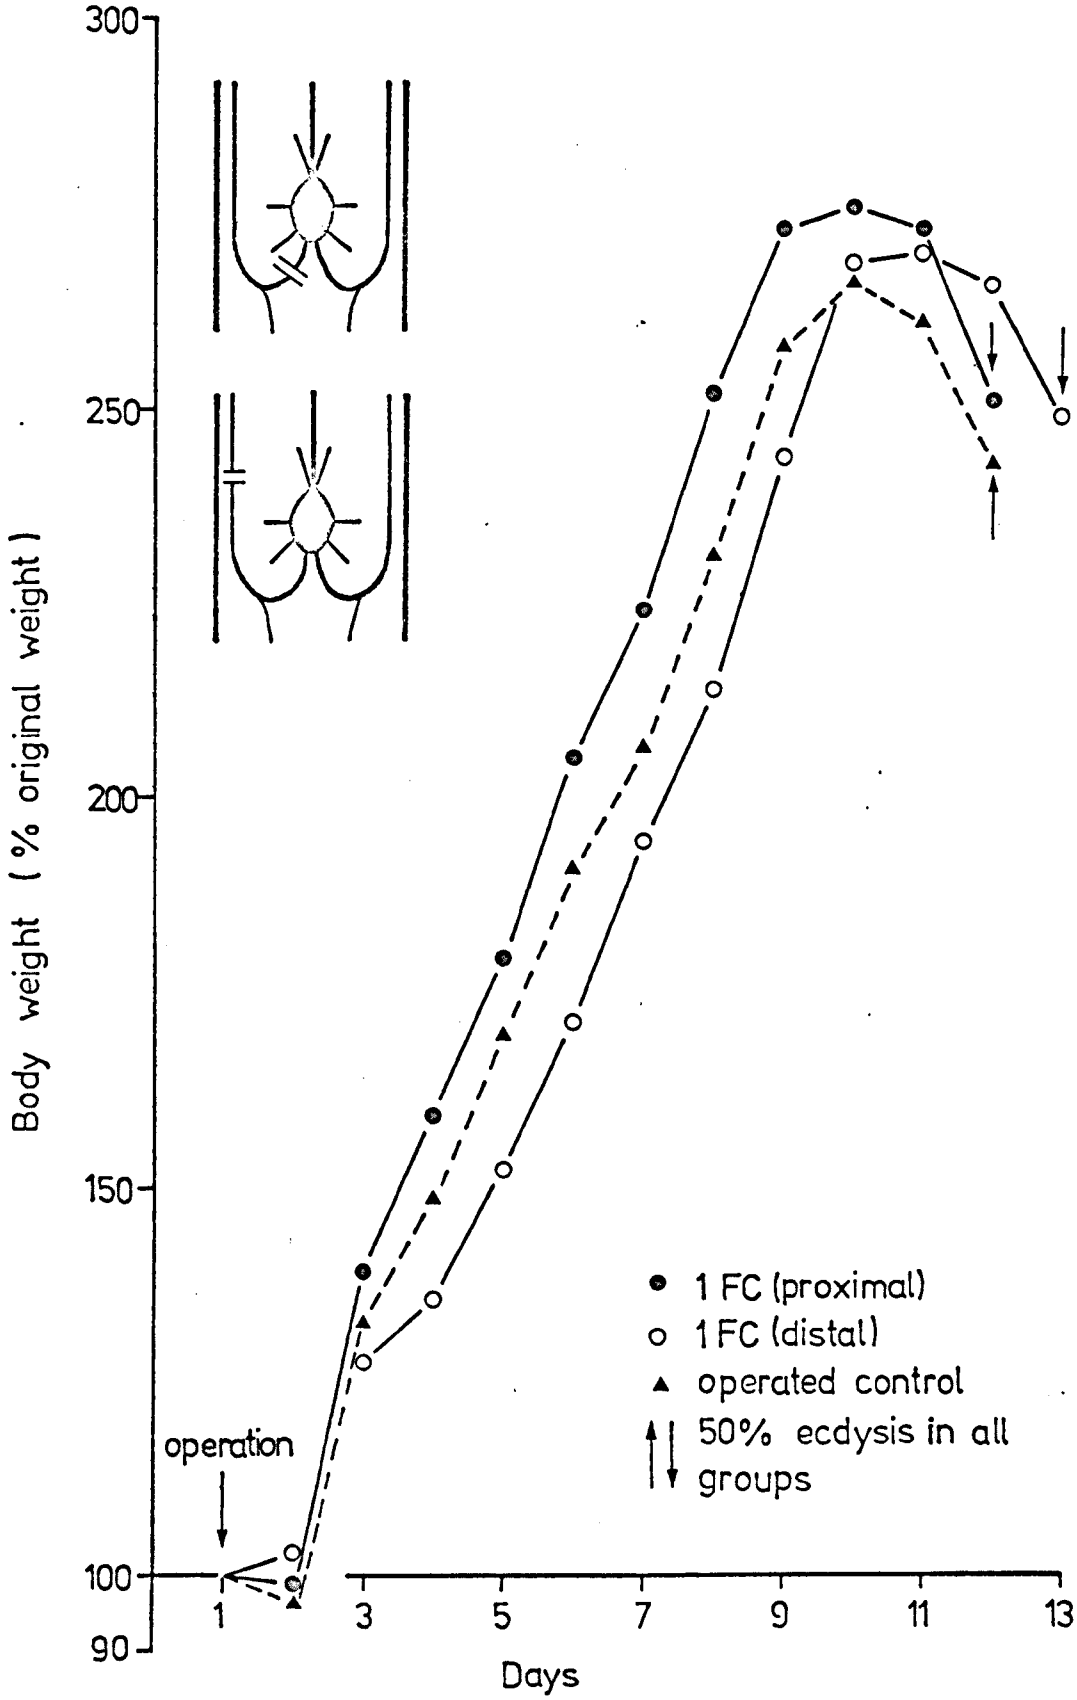

FIG 7. Growth after severance of one frontal connective (proximal), one frontal connective (distal).

Conclusions

In accordance with CLARKE and LANGLEY (1963c), the cutting of one frontal connective has no adverse effect upon the growth and moulting cycle.

Experiment 4.

The effect of cutting two frontal connectives (proximal to branches) on growth and moulting

The experimental treatments were as follows:

(a)	Both frontal connectives cut (proximal to branches)	47 animals
(b)	Operated controls	20 animals

Results

The 39 operated animals surviving beyond Day 6 can be divided into five groups according to their growth and moulting responses:

(i) Growth and attempted moulting

15 animals exhibited true growth and died between Days 15 and 20 while attempting to moult to adults. The growth rate of these animals was much lower than that of the controls and the attempted moult was made on average five days after the controls had successfully moulted (Fig. 8). Table 4 shows that the mean maximum percentage weight increase of group (i) operated animals was significantly lower than that of the controls.

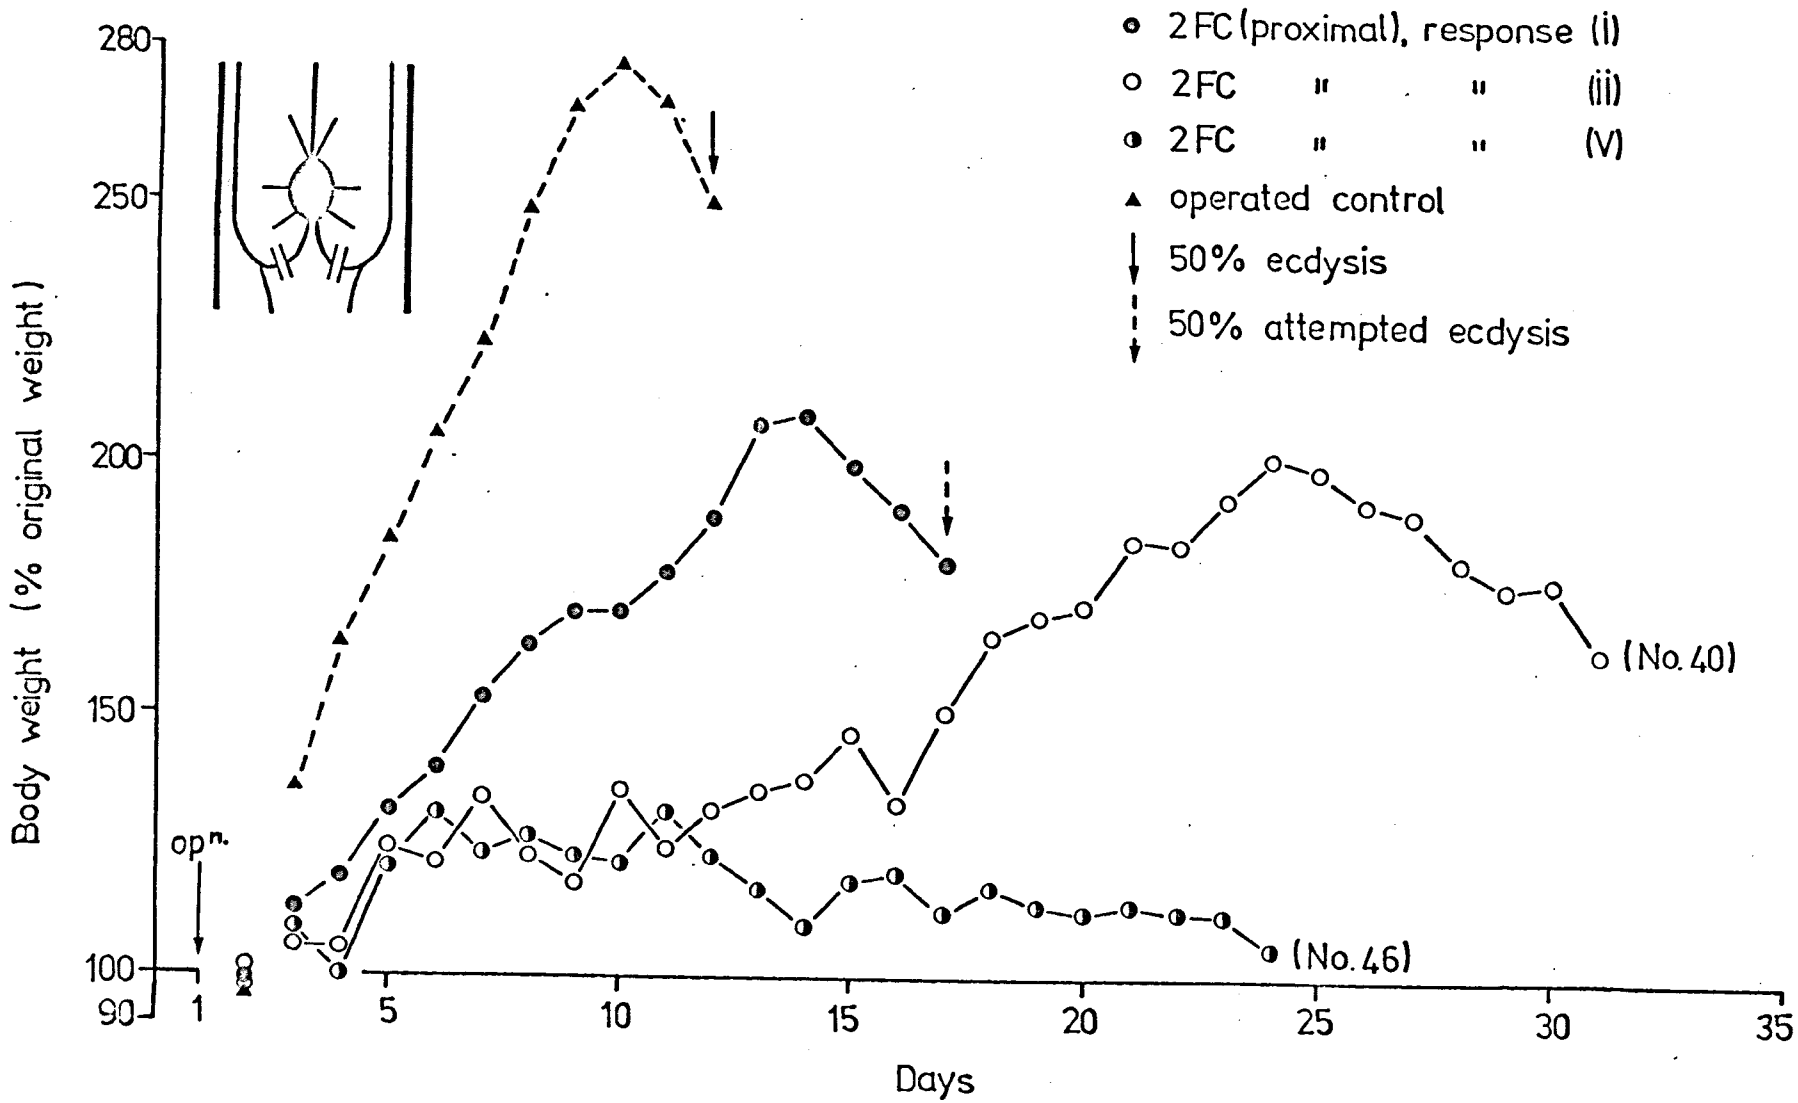

FIG 8. Growth after severance of two frontal connectives (proximal).

TABLE 4. Comparison of the mean maximum percentage weight increases of group (i) operated animals and the controls

Treatment	Individuals	Mean	S.E.	t	'P'
2 FC's cut (proximal) group (i)	15	117	4	13.87	0.001
Controls	16	179			

The operated locust adopted a normal posture for moulting, with the head pointing downwards, but after several hours of endeavouring to escape from the old cuticle the exhausted animal fell to the floor and eventually died. The wing pads of some operated animals at the time of death were widely parted and the abdomen drawn up by approximately 5 mm from the tip of the old cuticle (Plate 26), while in others abdominal retraction only was manifest (Plate 27).

8 operated locusts were X-rayed during their attempted moults and a representative sequence of radiographs from one particular individual (No. 37) is presented as Plates 30-32. It is obvious that reduced amounts of air are present in the gut compared to the controls (Experiment 1). More air can be detected in the gut of animal No. 21 (Plate 33), but there was evidently still not enough for a successful moult. Air continued to enter the hindgut after the operation. Post-mortem examination of group (i) animals showed that food was usually absent from the crop, colon and rectum, but was present in the midgut and ileum.

31

32

33

(ii) Growth and no attempted moulting

Animal No. 40 increased its operation weight by a maximum of 101% and survived for 31 days (approximately three times the normal instar length) without ever forming a new cuticle. It can be seen from Fig. 8 that very little growth occurred during the first sixteen days post-operative, but that thereafter the growth curve resembled that of group (i) animals attempting to moult on Day 17.

(iii) Reduced growth and attempted moulting

Operated animals Nos. 38 and 45 showed maximum weight increases of 82% and 76% respectively before dying on Day 17 while attempting to moult to adults.

(iv) Reduced growth and no attempted moulting

7 animals exhibited maximum weight increases that were 50-100% above their operation weights. None of them ever developed a new cuticle.

(v) Little or no growth and no attempted moulting

The remaining 14 animals maintained a fairly constant weight until death and failed to develop a new cuticle. The weight changes of one such individual (No. 46) are illustrated in Fig. 8.

All of the operated animals leaked digestive fluid to the exterior via the mouth. Leaking frequently commenced as early as Day 2, and by Day 6 over 90% of the operated animals were losing fluid. Close inspection of these animals revealed that liquid escaping from the mouth quickly passed to the ventral region of the neck membrane and then to the dorsal

region. Some animals leaked more than others and in these individuals fluid could be detected along the lateral membranes of the abdomen.

Conclusions

Approximately one-third of the operated animals surviving beyond Day 6 exhibit a twofold or more increase in weight, develop a new cuticle, but fail in their attempt to moult to the adult stage. After the operation sensory impulses from the gut could still reach the brain and corpora cardiaca via the branches of the frontal connectives, and via the hypocerebral ganglion, NCC I pathway of STRONG (1966). On the motor side, the frontal connectives are obviously implicated in the processes of air intake and/or retention at ecdysis, and regurgitation.

CLARKE and LANGLEY (1963c) obtained a uniform growth response to the severance of both frontal connectives, the operated third instar nymphs maintaining a constant weight and failing to produce a new cuticle. Survival, however, was poor and this may have led to the elimination of potential growers. ROOME (1968), working with third instar Locusta nymphs and third and fourth instar Schistocerca gregaria nymphs, found that a few animals increased in weight and developed a new cuticle after the cutting of both frontal connectives. In Periplaneta americana the operation does not prevent normal crop emptying (DAVEY and TREHERNE, 1963), or growth and moulting by at least a few operated nymphs (ROOME, 1968). According to PENZLIN (1971), however, nymphal

Periplaneta are unable to moult successfully after the operation.

Experiment 5

The effect of cutting both frontal connectives (distal to branches) on growth and moulting

The experimental treatments were as follows:

(a)	Both frontal connectives cut (distal to branches)	24 animals
(b)	Operated controls	12 animals

Results

The operation was attended by an early high mortality, with 9 animals dead by Day 5. The rest survived for eleven or more days and can be divided into four groups according to their growth and moulting responses:

(i) Growth and attempted moulting

7 animals more than doubled their operation weights and died between Days 13 and 17 while trying to moult to adults. The attempted moult was made on average two days after its successful completion by the controls (Fig. 9). Table 5 shows that the mean maximum percentage weight increase of group (i) operated animals was significantly lower than that of the controls.

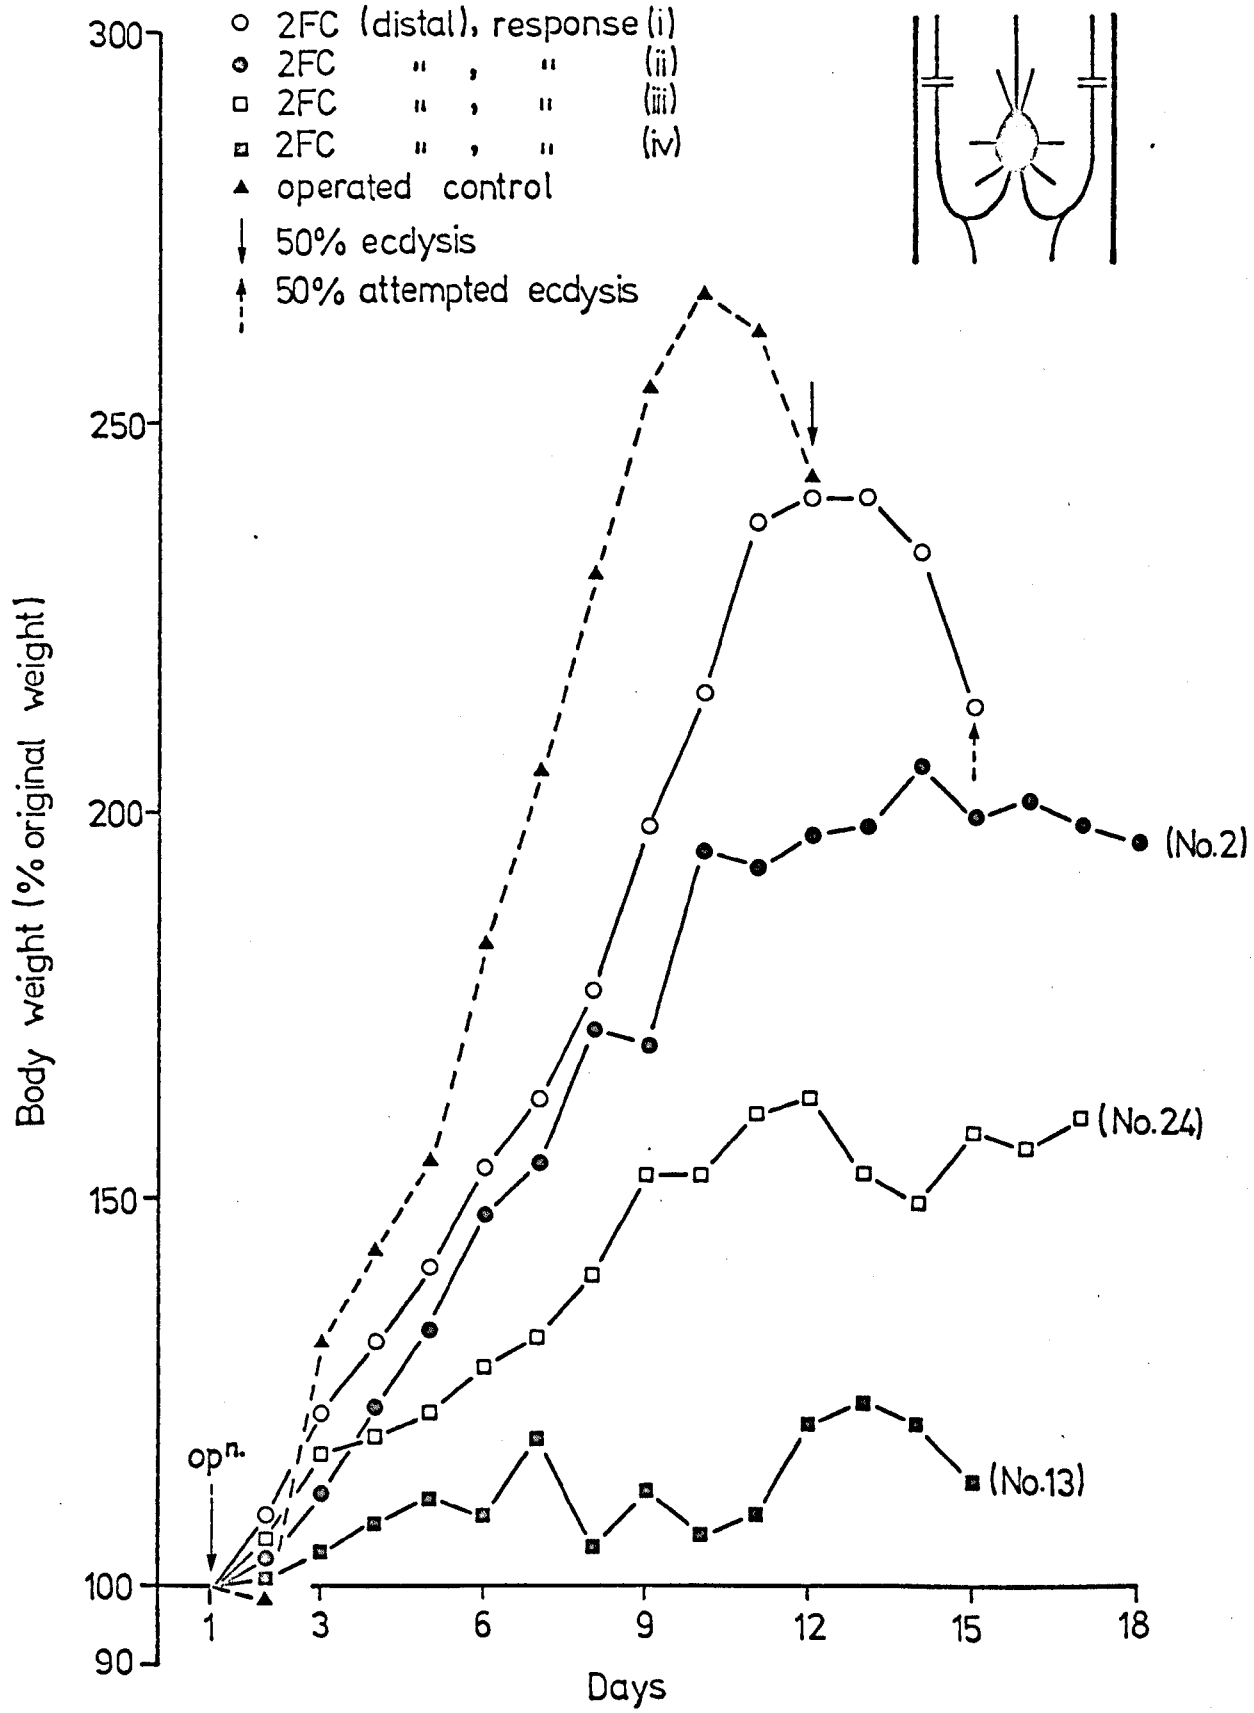

FIG 9. Growth after severance of two frontal connectives (distal).

TABLE 5. Comparison of the mean maximum percentage weight increases of group (i) operated animals and the controls

Treatment	Individuals	Mean	S.E.	t	'P'
2 FC's cut (distal) group (i)	7	132	10	3.50	0.01-0.001
Control	8	174	7		

Six operated animals were X-rayed over a period which covered the attempted moult and a sequence of radiographs from one representative individual (No. 5) is presented as Plates 34-37. It can be seen that the foregut contained only reduced amounts of air compared to the control animals at this time (Experiment 1), and that air continued to enter the hindgut after the operation. At autopsy food was always found in the midgut and ileum but not in the rest of the gut.

(ii) Growth and no attempted moulting

Operated animals Nos. 1 and 2 showed maximum weight increases of 105% and 106% respectively. The growth curve of No. 2 is presented in Fig. 9 where it can be seen that a period of growth during the first nine days is followed by a second period, also of nine days, during which a constant weight is maintained until death on Day 18. Neither animal developed a second cuticle.

PLATE 36. At the time of the attempted moulting.

PLATE 37. 8¼ hours after the attempted moult.

PLATES 34 – 37

34

35

36

37

(iii) Reduced growth and no attempted moulting

Group (iii) is comprised of three animals. The growth curve of No. 24, reminiscent in general shape to that of No. 2, is presented in Fig. 9. No group (iii) animal ever developed a new cuticle.

(iv) Little or no growth and no attempted moulting

Two animals maintained a fairly constant weight after the operation, and the growth curve of one of these (No. 13) is presented in Fig. 9. Neither animal developed a new cuticle.

Of the fifteen animals surviving beyond Day 6, twelve leaked digestive fluid through the mouth, the first observation being recorded on Day 3 for two animals.

Conclusions

60% of the operated animals surviving beyond Day 6 undergo true growth and this is a clear indication that sensory impulses from the foregut can reach the brain and corpora cardiaca along routes other than those involving the frontal connectives. The hypocerebral ganglion, NCC I pathway of STRONG (1966a) is still open after the operation, and the possible involvement of other, as yet unidentified, nervous pathways should not be ruled out. The involvement of the frontal connectives in the processes of air intake and/or retention, and regurgitation is confirmed in this experiment.

Experiment 6

The effect of cutting the anterior, median and posterior pharyngeal nerves on growth and moulting

The experimental treatments were as follows:

(a)	APNs, MPNs, and PPNs cut	36 animals
(b)	Operated controls	15 animals

Results

4 operated animals were dead by Day 6. The rest can be divided into three groups according to their growth and moulting responses.

(i) Growth and attempted moulting

26 animals exhibited true growth and died between Days 13 and 20 while endeavouring to moult to adults. The attempted moult was made on average three days after its successful completion by the controls (Fig. 10). Table 6 shows that the mean maximum percentage weight gain of group (i) operated animals was significantly lower than that of the controls. The weight changes of two individual locusts, Nos. 11 and 36, are included in Fig. 10 to illustrate the extremes of growth encountered.

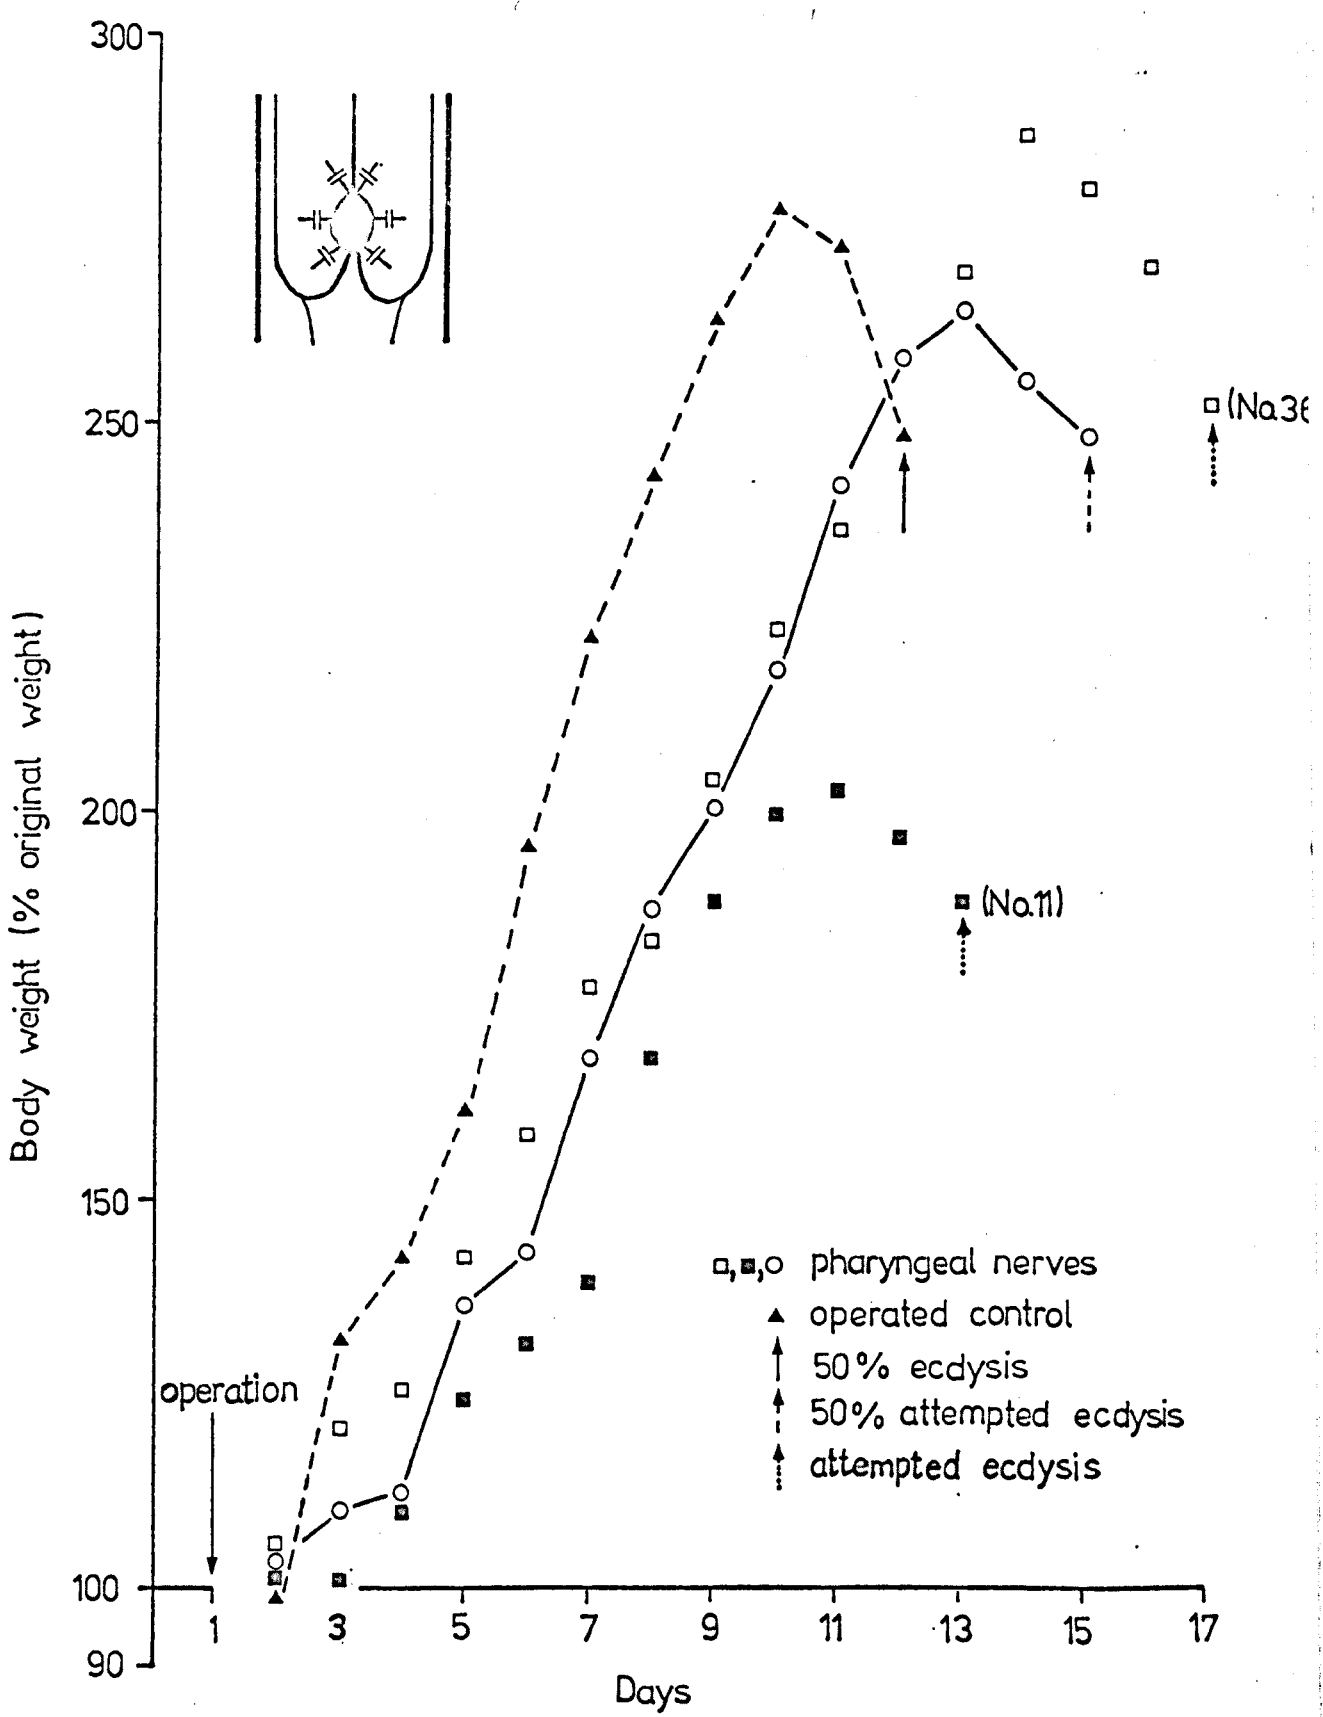

FIG 10. Growth after severance of anterior, median and posterior pharyngeal nerves.

TABLE 6. Comparison of the mean maximum percentage weight increases of group (i) operated animals and the controls

Treatment	Individuals	Mean	S.E.	t	'P'
APNs, MPNs and PPNs cut group (i)	26	158	4	3.60	0.001
Controls	12	176	3		

Ten operated locusts were X-rayed over a period covering the attempted moult, and a representative sequence of radiographs from one such animal (No. 16) is presented as Plates 38-41. It can be seen that reduced amounts of air are present in the foregut compared to the controls (Experiment 1), and that air continues to enter the hindgut. Post-mortem examination of group (i) animals indicated that food was usually absent from the crop, colon and rectum, but present in the midgut and ileum.

(ii) Growth and no attempted moulting

5 animals showed maximum body weight increases of between 118% and 166%. Two animals formed a new cuticle but died before making any attempt to moult. The other three animals failed to develop a new cuticle.

(iii) Reduced growth and no attempted moulting

Animal No. 38 increased its operation weight by a maximum of 92% before dying on Day 18 without ever forming a new cuticle.

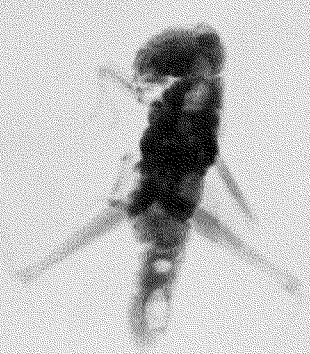
PLATES 38 – 41

38

39

40



41

Twenty-two of the thirty-two operated animals surviving beyond Day 6 leaked digestive fluid, some individuals starting to lose fluid as early as Day 2.

Conclusions

97% of the operated animals surviving beyond Day 6 increase their operation weights by a factor of two or more. According to CLARKE and LANGLEY (1963c), severance of the pharyngeal nerves in third instar nymphs leads to an immediate cessation of growth. In Periplaneta the operation interferes with crop emptying (DAVEY and TREHERNE, 1963), but in Leucophaea maderae severance of all the nerves connected to the frontal ganglion, except the recurrent nerve, does not affect this process (ENGELMANN, 1968). The results of Experiment 6 compare favourably with those reported in Section I where it was shown that pharyngeal nerve severance in adult animals has no adverse effect upon growth during the first ten days post-operative.

After the operation sensory impulses from the foregut can still reach the brain and corpora cardiaca via the branches of the frontal connectives, and via the hypocerebral ganglion, NCC I pathway of STRONG (1966). On the motor side, the pharyngeal nerves obviously exert a controlling influence over the processes of air intake and/or retention at ecdysis, and regurgitation.

In two animals the operation was unsuccessful with, in each case, a single posterior pharyngeal nerve remaining intact. That both animals were able to moult to adults

renders it likely that a full complement of pharyngeal nerves is not a necessary requisite for successful moulting. This point is taken up in the next experiment.

Experiment 7

The effect of cutting the anterior or posterior pharyngeal nerves on growth and moulting

The experimental groups were as follows:

(a)	Anterior pharyngeal nerves cut	18 animals
(b)	Posterior pharyngeal nerves cut	16 animals
(c)	Operated controls	10 animals

Results

2 treatment (a) and 5 treatment (b) animals were dead by Day 4. Those surviving beyond this time can be divided into three groups according to their growth and moulting responses.

(i) Growth and successful moulting

9 treatment (a) and 8 treatment (b) animals underwent true growth and moulted successfully to adults. Moulting in treatment (b) animals was delayed on average by two days compared to the controls (Fig. 11). Table 7 shows that the mean maximum percentage weight increases of the operated and control groups were not significantly different.

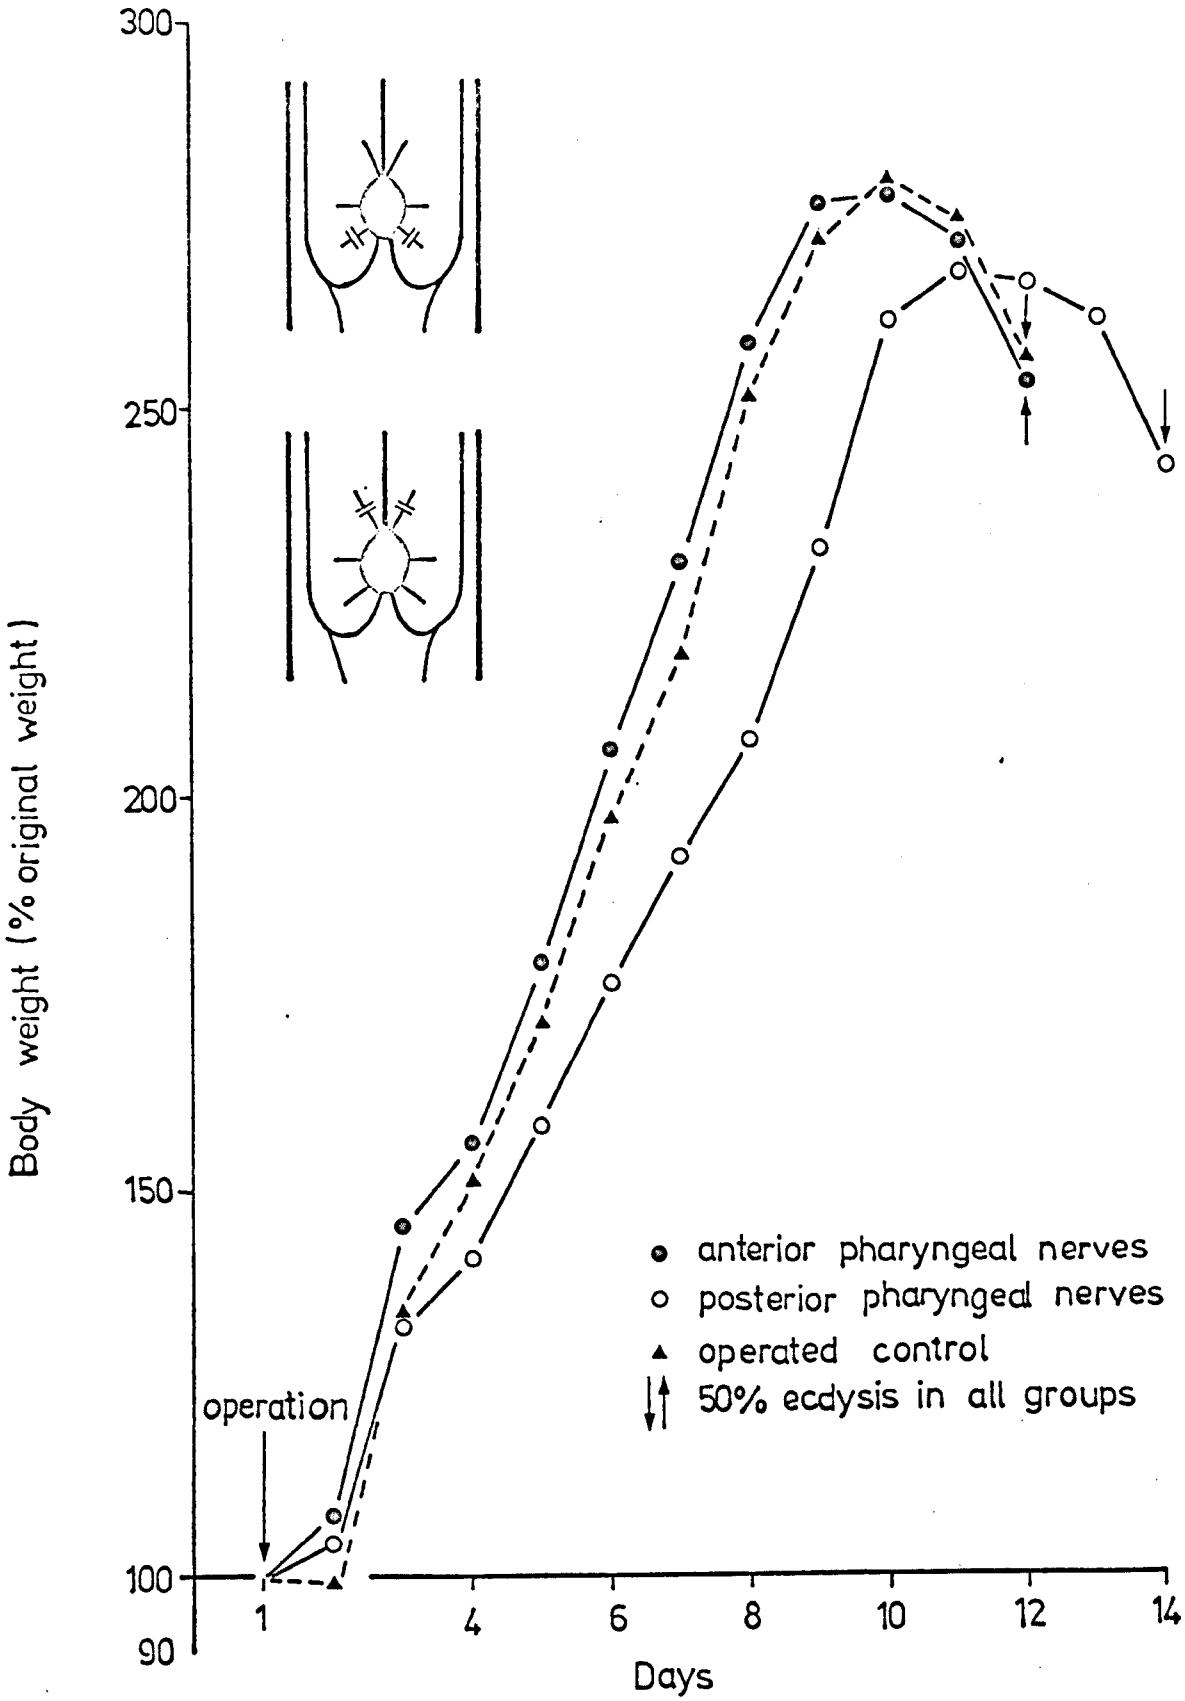


FIG 11. Growth after severance of anterior pharyngeal nerves, posterior pharyngeal nerves.

TABLE 7. Comparison of the mean maximum percentage weight increases of treatments (a) and (b) group (i) animals and the controls

Treatment	Individuals	Mean	S.E.		t	'P'
(a) APNs cut group (i)	9	179	5	(a):(b)	1.38	0.2-0.1
(b) PPNs cut group (i)	8	166	8	(a):(c)	-	
(c) Controls	9	179	3	(b):(c)	1.52	0.2-0.1

(ii) Growth and attempted moulting

6 treatment (a) and 2 treatment (b) animals underwent true growth and died between Days 12 and 16 while attempting to moult to adults. Table 8 shows that the mean maximum percentage weight increases of treatment (a) animals and the controls were not significantly different. The mean maximum percentage weight increase of the two treatment (b) animals was almost identical to that of treatment (a) animals and the controls.

TABLE 8. Comparison of the mean maximum percentage weight increases of treatments (a) and (b) group (ii) animals and the controls

Treatment	Individuals	Mean	S.E.		t	'P'
(a) APNs cut group (ii)	6	177	5			
(b) PPNs cut group (ii)	2	178	-	(a):(c)	0.34	0.8-0.7
(c) Controls	9	179	3			

(iii) Growth and no attempted moulting

Treatment (a) animal No. 3 and treatment (b) animal No. 3 exhibited maximum body weight increases of 186% and 101% respectively. Neither animal developed a second cuticle, the former dying on Day 16 and the latter on Day 10.

No treatment (a) or treatment (b) animal leaked digestive fluid at any time during the experimental period.

Conclusions

There exists a certain amount of individual variation in the moulting response to anterior or posterior pharyngeal nerve severance. The majority of animals in treatments (a) and (b) moult successfully to adults. In a few, however, both pairs of pharyngeal nerves need to be intact in order that successful moulting might take place. It is deduced that in these animals the moult fails because of a break-down in the neural mechanism co-ordinating the intake and/or retention of air at ecdysis.

Experiment 8

The effect of removing the frontal ganglion on growth and moulting

The experimental treatments were as follows:

(a)	Frontal ganglion removed	19 animals
(b)	Operated controls	8 animals

Results

The operated animals can be divided into four groups according to their growth and moulting responses.

(i) Growth and attempted moulting

Animals Nos. 3 and 15 showed maximum body weight increases of 104% and 118% respectively and died on Days 26 and 17 while attempting to moult to adults (Fig. 12). These weight increases were well below the mean maximum control increase of 175%.

Plate 42 is a radiograph of animal No. 3 taken at the time of attempted moulting. The moult failed because the insect was unable to empty its gut of food, a necessary preliminary to the swallowing of air. Despite being unable to split open the old cuticle, both group (i) operated animals made vigorous attempts to escape from it and this led to them assuming a shrunken appearance at death (Plate 29). Plates 44-47 are radiographs of four frontal ganglionectomised fourth instar nymphs (from Section III) which were taken at the time of their attempted moults. Food can again be seen to occupy most of the gut, although in three individuals air is detectable in the rectum. The above remarks concerning gut contents were confirmed on dissection.

(ii) Reduced growth and attempted moulting

Animal No. 7 increased its body weight by a maximum of 82% and died on Day 17 while attempting to moult. Plate 43 shows that this insect was unable to empty its gut of food at the time of moulting.

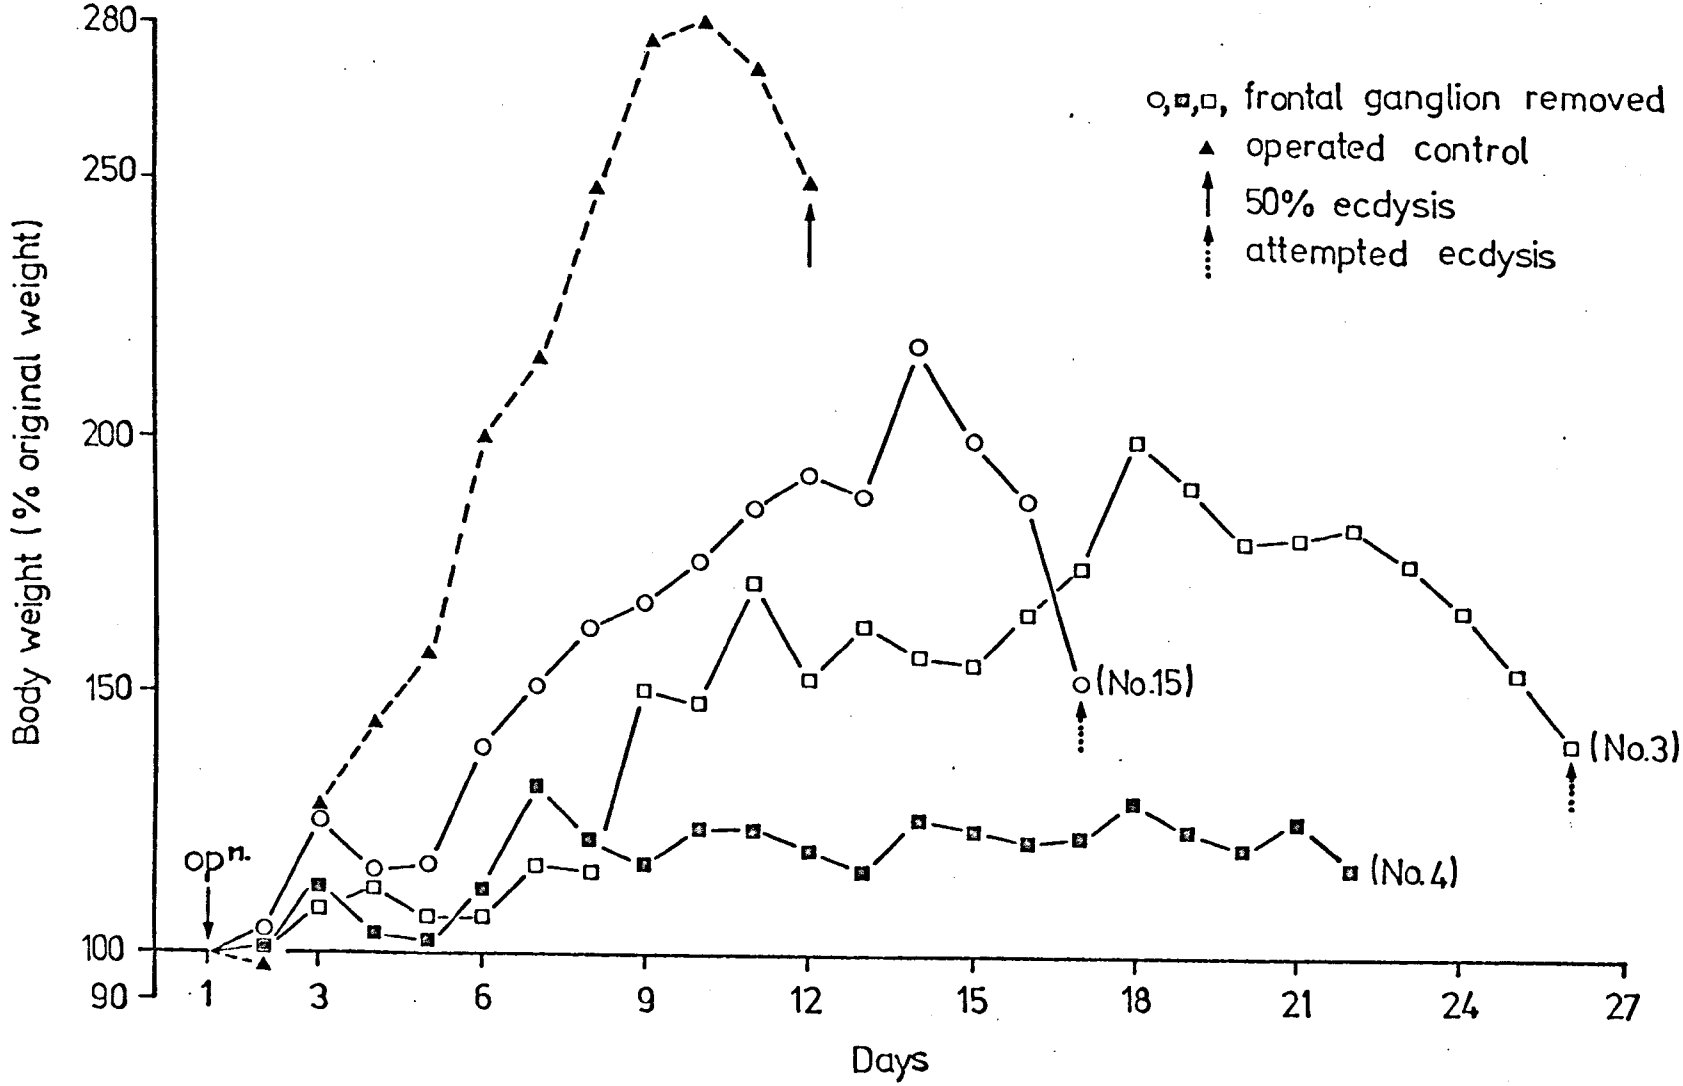

FIG 12. Growth after removal of the frontal ganglion.

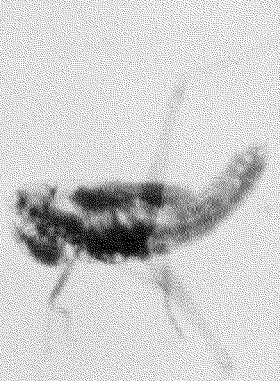
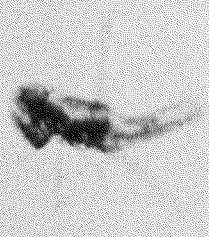
PLATES 42 - 47

42

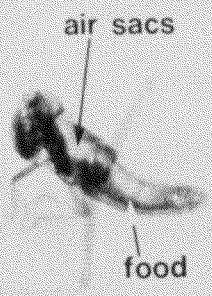


43

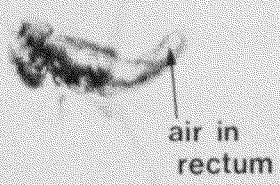
44



45



46



47

(iii) Reduced growth and no attempted moulting

3 animals showed maximum body weight increases of between 56% and 82% and failed to develop a new cuticle.

(iv) Little or no growth and no attempted moulting

13 animals maintained an approximately constant weight, and the growth curve of one such individual (No. 4), which survived for twice the normal instar length without ever forming a new cuticle, is presented in Fig. 12.

All of the operated animals leaked digestive fluid through the mouth, and in some leaking commenced as early as Day 2. The fluid dried on contact with the air, causing the head and thoracic regions in particular to become caked with the substance, so producing a picture consistent with that recorded by GILLOTT (1964) and ROOME (1968).

Conclusions

According to CLARKE and LANGLEY (1963b, c) frontal ganglionectomy in third instar nymphs causes every operated animal to maintain a constant weight. ROOME (1968), however, obtained essentially similar results to those described here, the majority of his frontal ganglionectomised third and fourth instar Locusta nymphs maintaining a constant weight, but a few showing fairly considerable weight increases after the operation. This author found that removal of the frontal ganglion in fourth instar Schistocerca nymphs caused them either to maintain a constant weight or to lose weight.

For continued growth to occur after the operation sensory impulses from the foregut must be reaching the brain

and corpora cardiaca along routes other than those involving the frontal ganglion. These may include the branches of the frontal connectives, and also the hypocerebral ganglion, NCC I route of STRONG (1966).

The frontal ganglion obviously plays an important role in co-ordinating emptying of the foregut at ecdysis. The rectum of a few fourth instar individuals was devoid of food and did, in fact, contain air. This is convincing proof that air does enter the hindgut through the anus at moulting. Its entry is most probably controlled by abdominal nerves running from the last abdominal ganglion to the rectum (ALBRECHT, 1953).

The progress of the moulting cycle is arrested in the majority of the operated animals and retarded by varying degrees in the rest. Animal No. 3, in attempting to moult on Day 26, took twice as long to reach this stage as did the controls. Animals Nos. 7 and 15, on the other hand, did not show such a lengthy delay, endeavouring to moult on Day 17 in each case.

Experiment 9

The effect of cutting (a) one labral nerve, and (b) both labral nerves on growth and moulting

The labral nerves, which probably contain both motor and sensory fibres, leave the tritocerebral ganglia and innervate the labrum and some of the dorsal muscles of the pharynx (SNODGRASS, 1926, 1935). In Periplaneta (WILLEY, 1961) the

labrum is also innervated by branches of the frontal connectives. The labral nerve in this insect has been shown by WILLEY to be of composite origin, coming partly from cells within the tritocerebrum and sub-oesophageal ganglion, and partly from fibre tracts of the protocerebrum. In Locusta, as in Periplaneta, each labral nerve fuses with its fellow frontal connective to form a short labro-frontal nerve root which then enters the tritocerebrum. Thus, although not forming part of the stomatogastric nervous system, the labral nerves are intimately associated with one of its components. In Experiment 9 the effects upon growth and moulting produced by severing one or both labral nerves are tested.

The experimental treatments were as follows:

(a)	One labral nerve cut	10 animals
(b)	Both labral nerves cut	24 animals
(c)	Operated controls	10 animals

Results

The severance of one labral nerve had no adverse effect upon the growth and moulting cycle (Fig. 13, Table 9).

An early high mortality attended severance of both labral nerves and eleven of the operated animals were dead by Day 6. Those surviving beyond this time can be divided into four groups according to their growth and moulting responses.

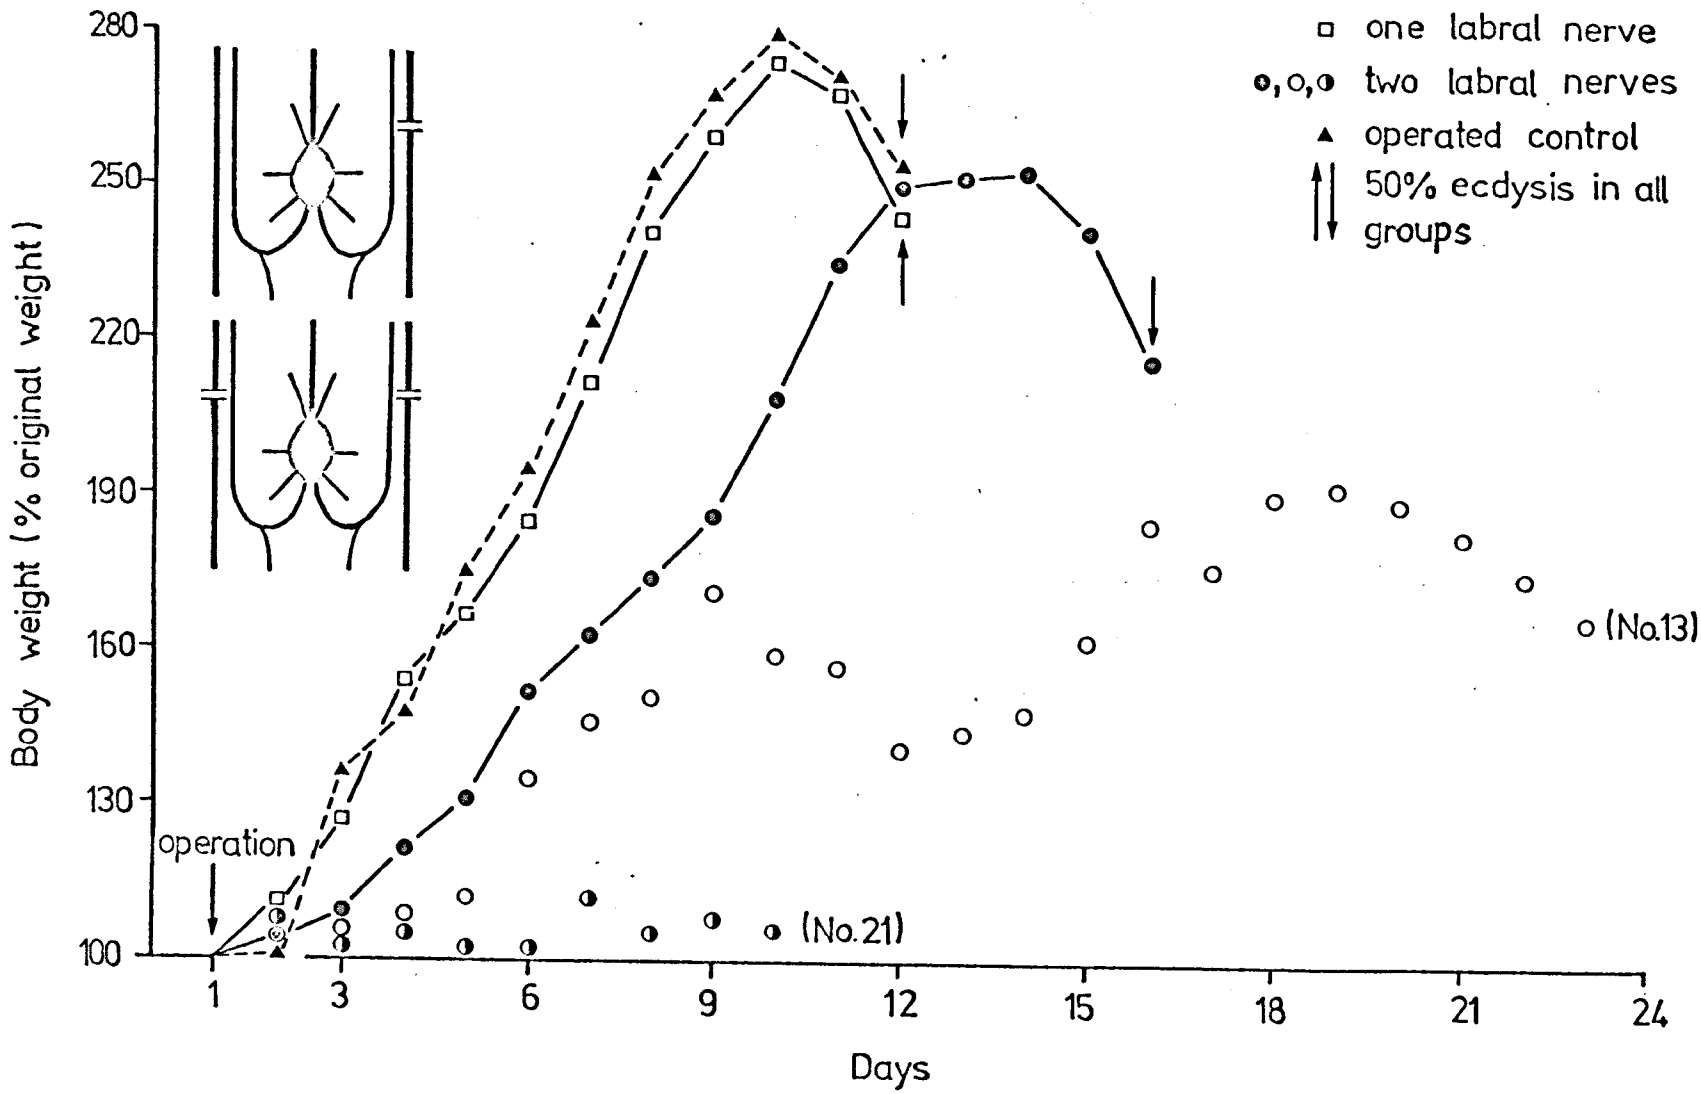


FIG 13. Growth after severance of one labral nerve, two labral nerves.

(i) Growth and successful moulting

6 animals underwent true growth and moulted to adults, though an average four days later than the controls (Fig. 13). Table 9 shows that the mean maximum percentage weight increase of these animals was significantly lower than that of treatment (a) animals and the controls.

(ii) Growth and no moulting

Animals Nos. 1 and 23 exhibited maximum body weight increases of 126% and 121% respectively. Both formed a new cuticle but died without ever attempting to moult.

(iii) Reduced growth and no moulting

3 animals showed maximum body weight increases that were 50-100% above their operation weights. No animal in this group ever developed a new cuticle, although No. 13 survived for more than twice the normal instar length (Fig. 13).

(iv) Little or no growth and no moulting

2 animals maintained an approximately constant weight after the operation, one for eight and the other for nine days. The weight changes of the latter animal are presented in Fig. 13. Neither animal ever developed a new cuticle.

Grass accumulated in the preoral food cavity of five treatment (b) animals (Table IX of the Appendix) forcing the labrum upwards and away from its normal resting position. Labrum displacement was a temporary phenomenon and neither growth nor moulting were prevented by it. No treatment (a) or treatment (b) animal leaked digestive fluid at any time during the experiment.

Conclusions

True growth can occur in the absence of sensory information normally carried by the labral nerves. It is assumed here that the labral nerves in Locusta normally carry sensory information from the A_1, A_2, and A_3 receptors of the clypeolabrum (THOMAS, 1966). HASKELL and MORDUE (1969) have shown that cautery of the $A_1 + A_2$ receptors, or cautery of the A_3 receptors, does not seriously affect feeding behaviour. After labral nerve severance the central nervous system can still receive phagostimulatory input from the H receptors on the hypopharynx, and from the dome receptors on the labral and maxillary palps, which regions are innervated by nerves from the sub-oesophageal ganglion (ALBRECHT, 1953).

On the motor side, the cutting of both labral nerves interferes with the role of the labrum in assisting entry of food into the mouth. The accumulation of food in the preoral food cavity is, however, only a temporary phenomenon, and in the absence of the labral nerves, the branches of the frontal connectives may control movement of the labrum.

Summary and Conclusions to Section II

1. A summary of the results of the various operations performed in this section is presented in Table 10.

2. True growth (minimum twofold increase in body weight) can occur after the severance of both frontal connectives, after the severance of the anterior, median and posterior pharyngeal nerves, and after the removal of the frontal ganglion. These results should be compared with those of CLARKE and LANGLEY (1963b, c) who state that the above operations lead to a complete cessation of growth in third instar nymphs.

3. Sensory information from the foregut can reach the brain and corpora cardiaca along nervous pathways which do not involve the frontal ganglion. These may include the branches of the frontal connectives, the hypocerebral ganglion ⟶ NCC I pathway of STRONG (1966), and other as yet unidentified routes.

* ANIMALS NOT EXHIBITING HYPERPHAGIC-TYPE RESPONSE

4. The frontal ganglion co-ordinates emptying of the foregut at ecdysis.

5. A motor pathway involving the frontal connectives, the frontal ganglion, and the pharyngeal nerves is implicated in the control of air intake and/or retention at ecdysis. This same pathway also controls regurgitation.

6. The labral nerves are not involved in the control of growth and moulting.

SECTION III

THE EFFECT OF FRONTAL GANGLIONECTOMY ON FOOD PASSAGE AS MEASURED BY FAECES PRODUCTION

There is much evidence to suggest that frontal ganglionectomy interferes with the movement of food through the gut. In immature adult female Schistocerca gregaria removal of the frontal ganglion inhibits emptying of the foregut (HIGHNAM et al., 1966); the amount of food passed through the gut of these animals, as measured by faeces production, is greatly reduced (HILL et al., 1966). The operation has a similar effect on crop emptying and faeces production in immature adult female Melanoplus differentialis (GILLOTT et al., 1970; DOGRA and EWEN, 1971) and adult male and female Gryllus bimaculatus (ROUSSEL, 1966).

On the other hand, CLARKE and LANGLEY (1963b) and CLARKE and GILLOTT (1965) report that food intake and defaecation proceed normally in third instar Locusta nymphs after removal of the frontal ganglion. Immature adult female Necrophorus vespillo were observed by ROUSSEL (1966) to feed normally and to show an increase in body weight after frontal ganglionectomy. However, with the exception of HILL et al. (1966), none of the above authors include any quantitative measurements of feeding activity.

ROOME (1968) has shown that frontal ganglionectomy in third and fourth instar Locusta nymphs leads to a significant

drop in food consumption and faeces production in the majority of operated animals. This effect is related to an observed accumulation of food in the crop at autopsy and to an absence of any real growth. In a few operated individuals, however, positive growth is identified and is associated with an increase in faeces production.

The results of Experiment 8 (Section II) demonstrate the variable effect of frontal ganglionectomy upon the growth and moulting cycle in fifth instars. Thus while the majority of operated animals maintain a constant weight and fail to develop a new cuticle, a few grow, form a new cuticle and then die while attempting to moult to the adult stage. Casual observation of faeces production indicated that the former group of animals were passing more food through the gut than the latter group

In Section III the various growth responses to frontal ganglionectomy are related to food passage through the gut, as measured by faeces production. The frontal ganglion was removed, without the addition of any Ringer solution, from newly moulted fourth and fifth instar Locusta nymphs of both sexes. Operated and control animals were weighed daily and their faeces collected, dried at 100°C for 24 hr and then weighed. Operative technique and post-operative care were as described in Chapter II. ROOME (1968) has investigated faeces production in short-lived (dead before Day 10) frontal ganglionectomised Locusta nymphs. Therefore only those operated animals surviving for longer than ten days are considered here.

Fifth Instars

Fifty-four newly moulted fifth instar nymphs of both sexes were sampled from a stock cage; the frontal ganglion was removed from thirty-eight animals (16 m, 22 f) and sixteen animals (7 m, 9 f) served as controls.

The controls had an instar length of 12 to 13 days (Figs. 17 and 18), compared to the 10 days of normal unoperated animals. The delay in moulting can be attributed to the post-operative treatment of the controls. Control female locusts passed more food through the gut per day than control males and were correspondingly larger and heavier (Table 21). Faeces production in both sexes reached a peak during the middle period of the instar (Figs. 19 and 20), a result agreeing with that of DAVEY (1954) for unoperated fifth instar Schistocerca nymphs.

Eight operated animals died before Day 10 and were discarded. The rest survived for longer than ten days and are divided into four groups according to their growth and moulting responses:

(a) Growth (at least 100% increase in weight) and attempted moulting

Thirteen animals grew, though at a reduced rate when compared to the controls (Figs. 17 and 18), and developed a new cuticle underneath the old one. They all died, between Days 14 and 22, while attempting to moult to the adult stage. The condition of the gut of these animals at autopsy is

summarized in Table 22. It is clear that frontal ganglionectomy prevents normal emptying of the foregut prior to swallowing of air at ecdysis. Air was, however, observed in the rectum of a few individuals.

Group (a) operated animals of both sexes passed less food through the gut per day than the controls and their body weight increases were correspondingly lower (Table 21). The operated peak in faeces production was lower than the control peak and appeared later (Figs. 19 and 20). In general it was found that the longer the operated instar period, the later was the appearance of the peak in faeces production. Thus operated female No. 1 died trying to moult on Day 22 and showed a faeces peak on Day 18, while operated Male No. 13 attempted to moult on Day 14 and exhibited a faeces peak on Day 9, just one day later than the control peak (Table X of the Appendix).

(b) Growth (at least 100% increase in weight) and no attempted moulting

Two females grew, but at a reduced rate compared to the controls (Fig. 18), and died without forming a new cuticle. At autopsy the foregut, midgut and ileum of female No. 15 (survived for sixteen days) was packed full of grass, while the gut of female No. 14 (survived for twenty-two days) contained more normal amounts of food (Table 22). Despite the distended state of its gut, female No. 15 expelled a greater weight of faeces per day than female No. 14 (Table X of the Appendix). Daily faeces production and body weight increase were both reduced in comparison to group (a) operated females (Table 21, Fig. 20).

Scoring of gut contents:

+, Very little food +++++, Gut distended with food;

-, Food absent; Rm, Red material.

(c) Reduced growth (50-100% increase in weight) and no attempted moulting

Four males and four females exhibited weight increases that were 50-100% above their operation weights (Figs. 17 and 18). None of them ever developed a new cuticle. The foregut of the majority of animals was packed full of grass at autopsy and in some cases the midgut and ileum were also distended with food (Table 22). The reduced growth rate of group (c) operated animals was associated with a drop in the daily production of faeces (Table 21, Figs. 19 and 20).

(d) Little or no growth (0-50% increase in weight) and no attempted moulting

Two males and five females maintained an approximately constant weight after removal of the frontal ganglion (Figs. 17 and 18) and did not develop a new cuticle. The foregut of every individual was found to be distended with undigested food at autopsy (Table 22). Group (d) operated animals maintained a constant, low level of faeces production throughout their lives (Figs. 19 and 20), and this was associated with a low weight increase (Table 21). The peak in faeces production, so obvious in control and group (a) operated animals, was completely suppressed in groups (c) and (d) operated animals.

Fourth Instars

Forty-two newly moulted fourth instar nymphs of both sexes were sampled from a stock cage; thirty animals (15 m, 15 f) had the frontal ganglion removed and twelve (6 m, 6 f) served as controls.

The controls had an instar length of 9 days (Figs. 21 and 22) compared to the 7 days of normal unoperated animals. As in fifth instars the delay in moulting can be attributed to the post-operative treatment of the controls. Control females passed more food through the gut per day than control males and were correspondingly larger and heavier (Table 21). A single, mid-instar peak in faeces production is recorded for operated control fourth instar Locusta females (ROOME, 1968) and for unoperated fourth instar Schistocerca nymphs (DAVEY, 1954). Two peaks in faeces production were manifest in the control males of the present experiment and although a single peak was evident in the control females it did not appear until two days before the moult (Figs. 23 and 24).

Thirteen operated animals died before Day 10 and were discarded. The rest survived for longer than ten days and are divided into four groups according to their growth and moulting responses:

(a) Growth (at least 100% increase in weight) and attempted moulting

One male (No. 2) and one female (No. 1) exhibited weight increases in excess of 100% of their original weights,

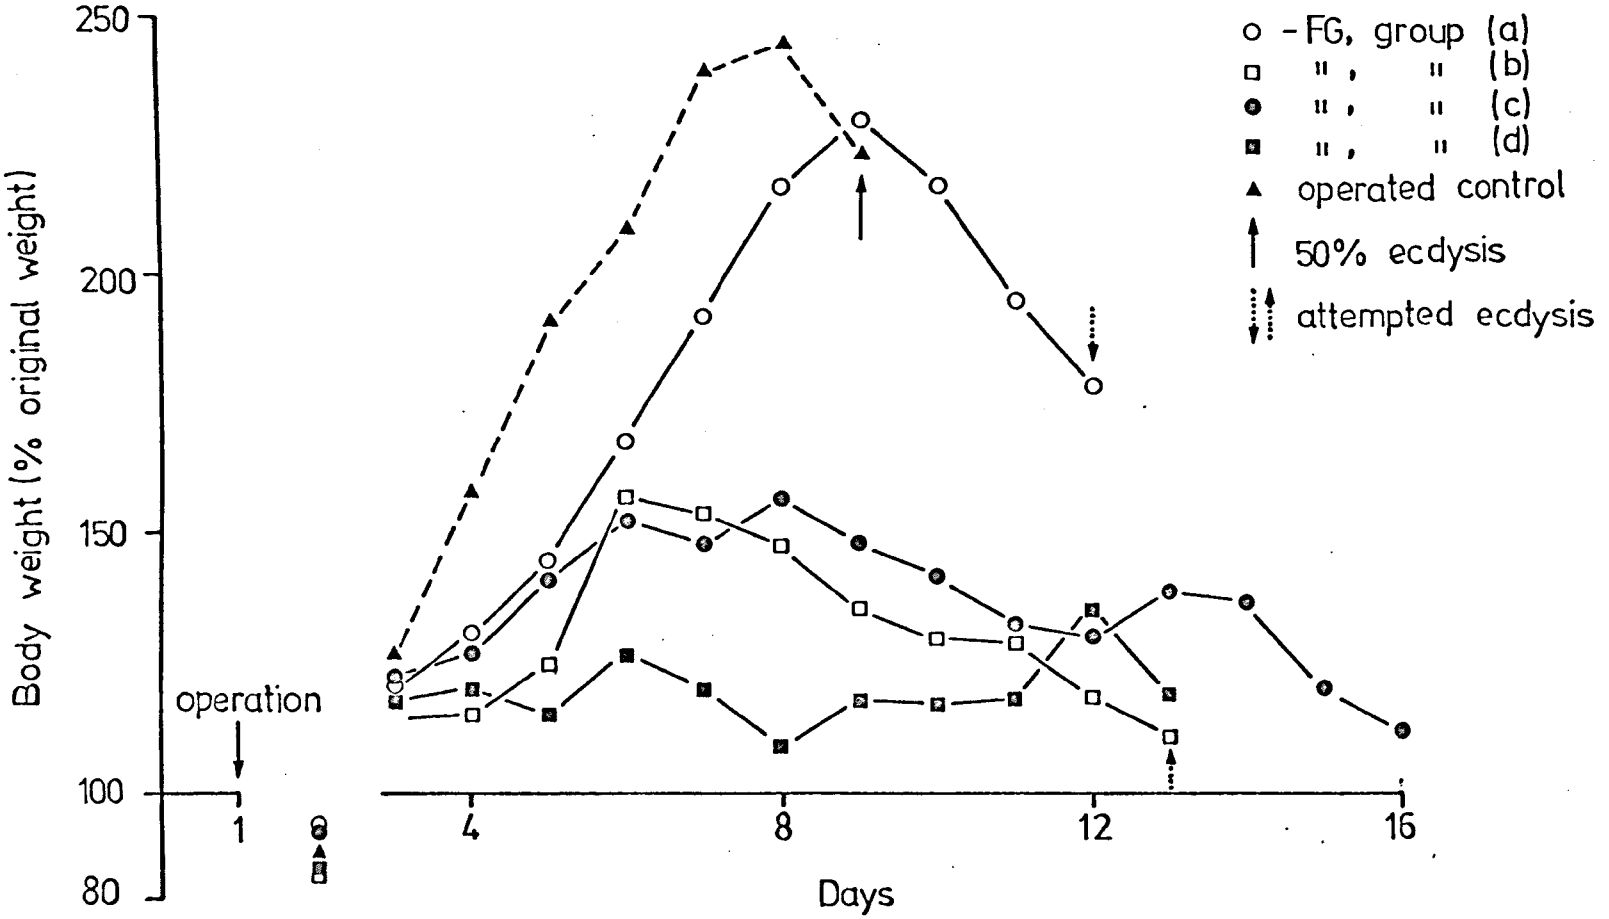

FIG 21. Growth after removal of the frontal ganglion (4th instar, ♂).

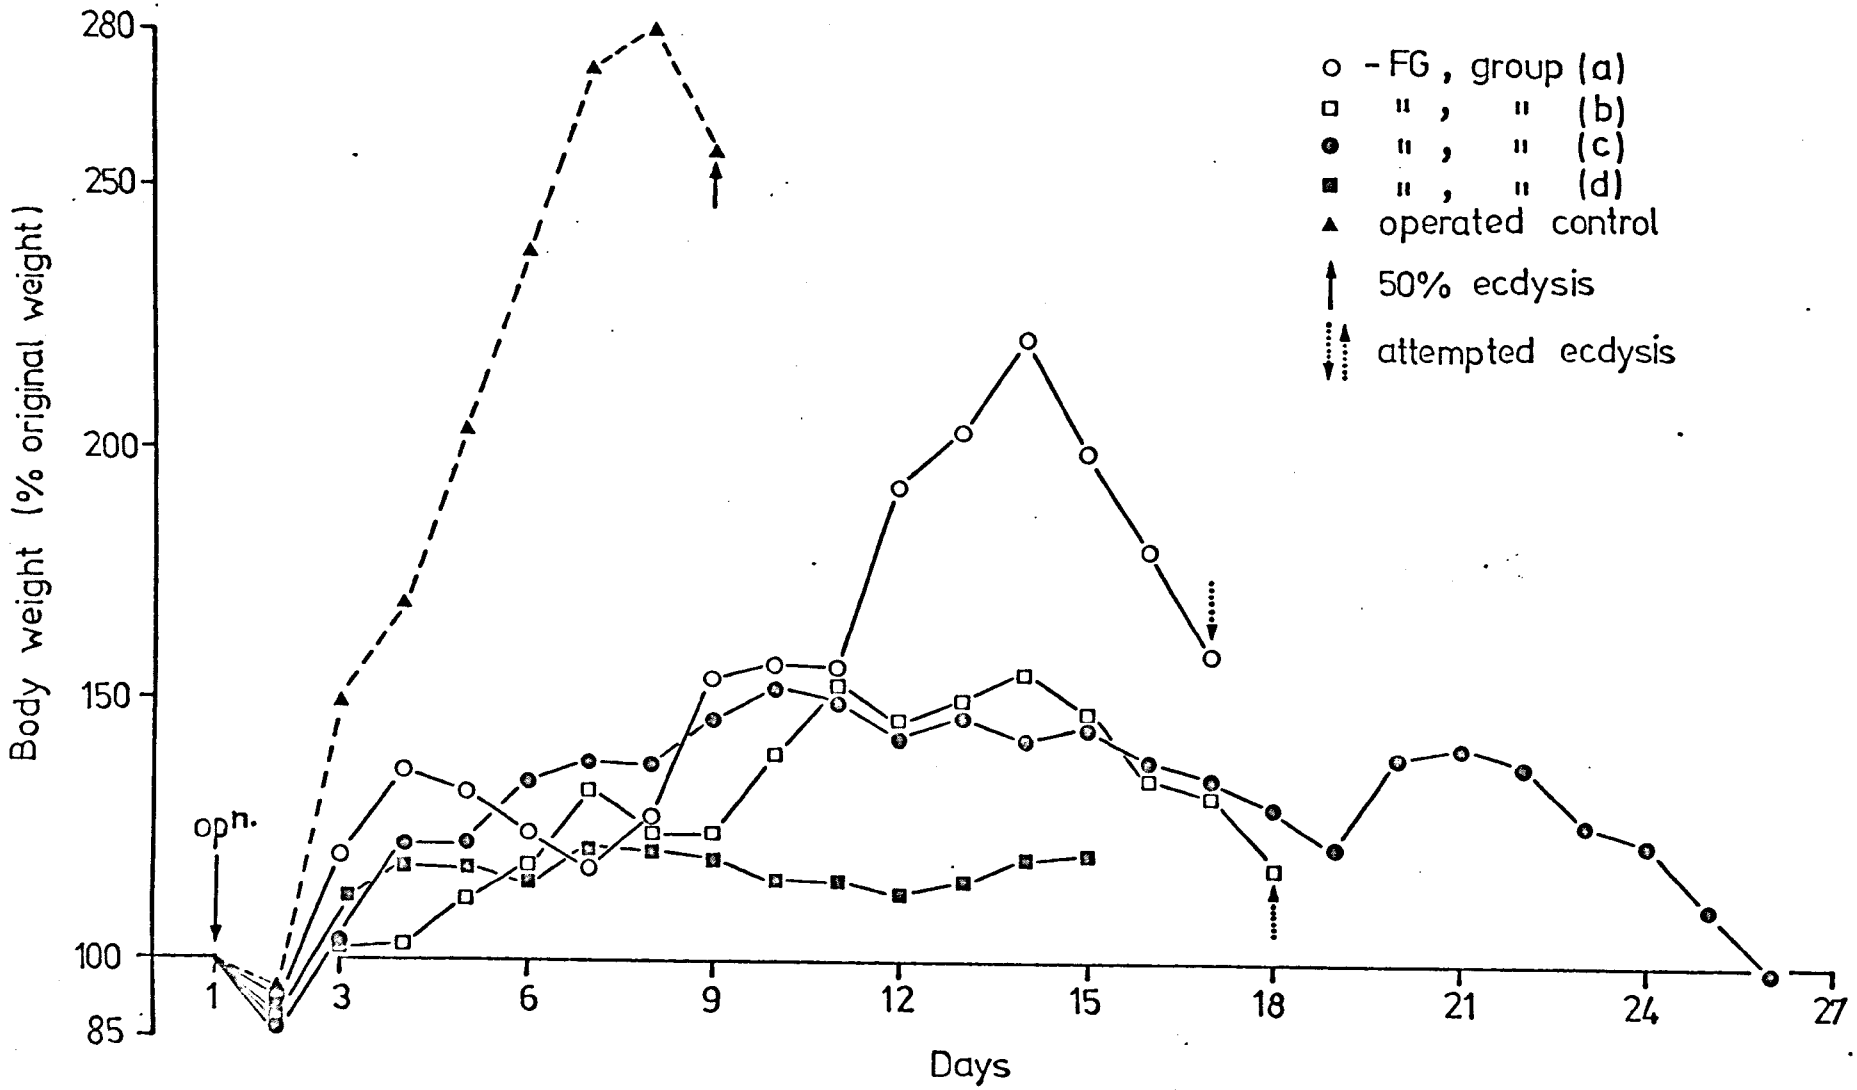

FIG 22. Growth after removal of the frontal ganglion (4^{th} instar, ♀).

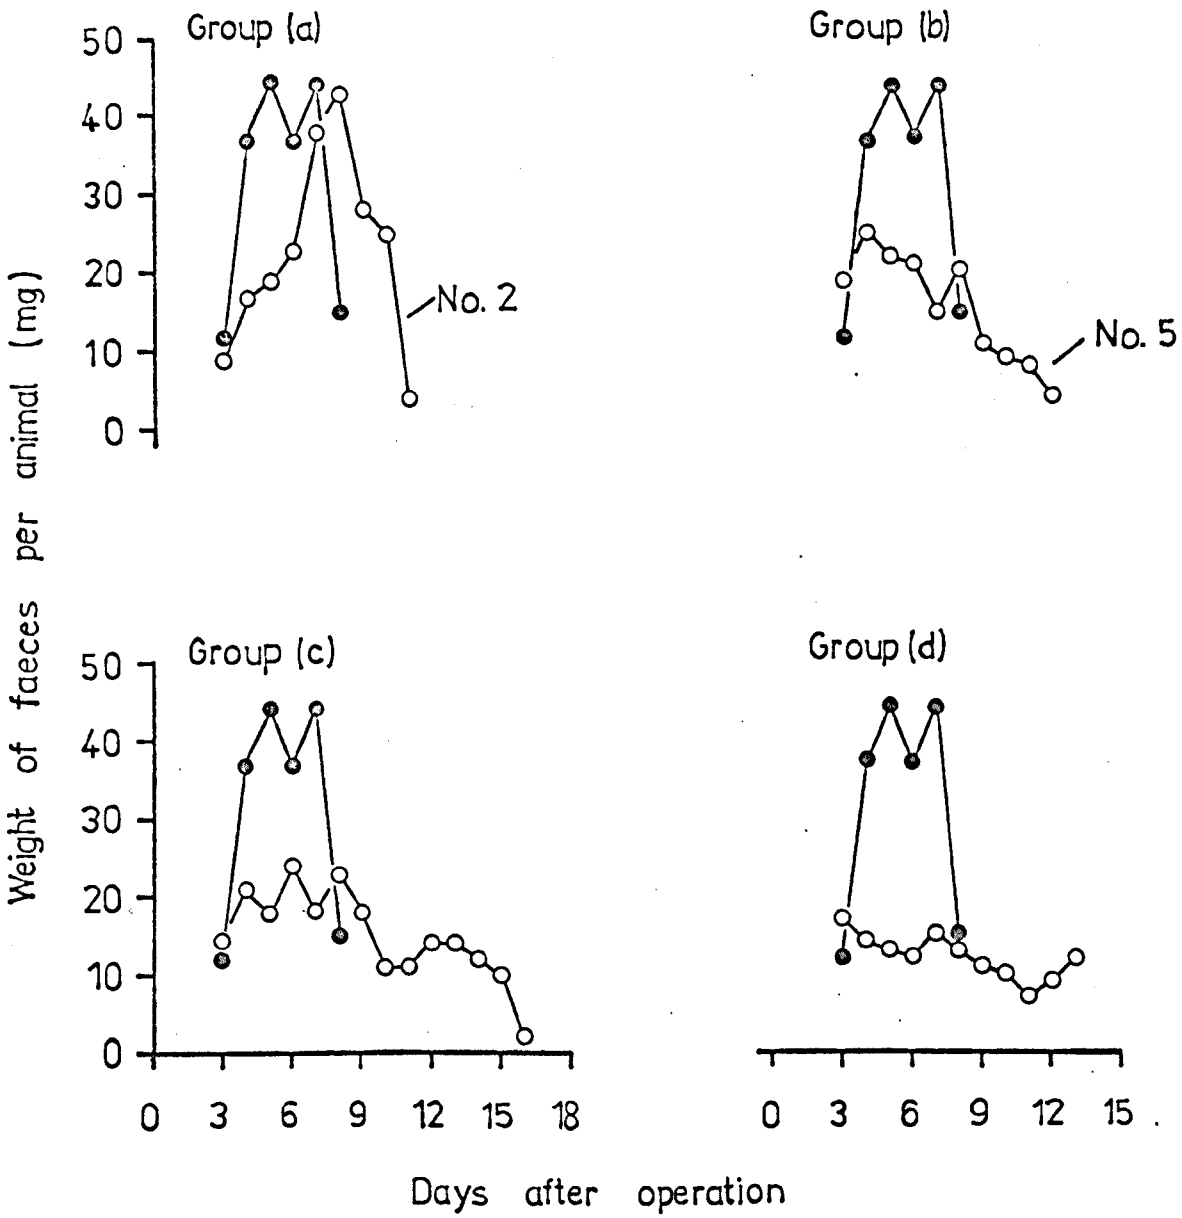

Fig 23. The weight of faeces produced per animal per day following frontal ganglionectomy of fourth instar males. o— frontal ganglionectomized animals; ●— control animals.

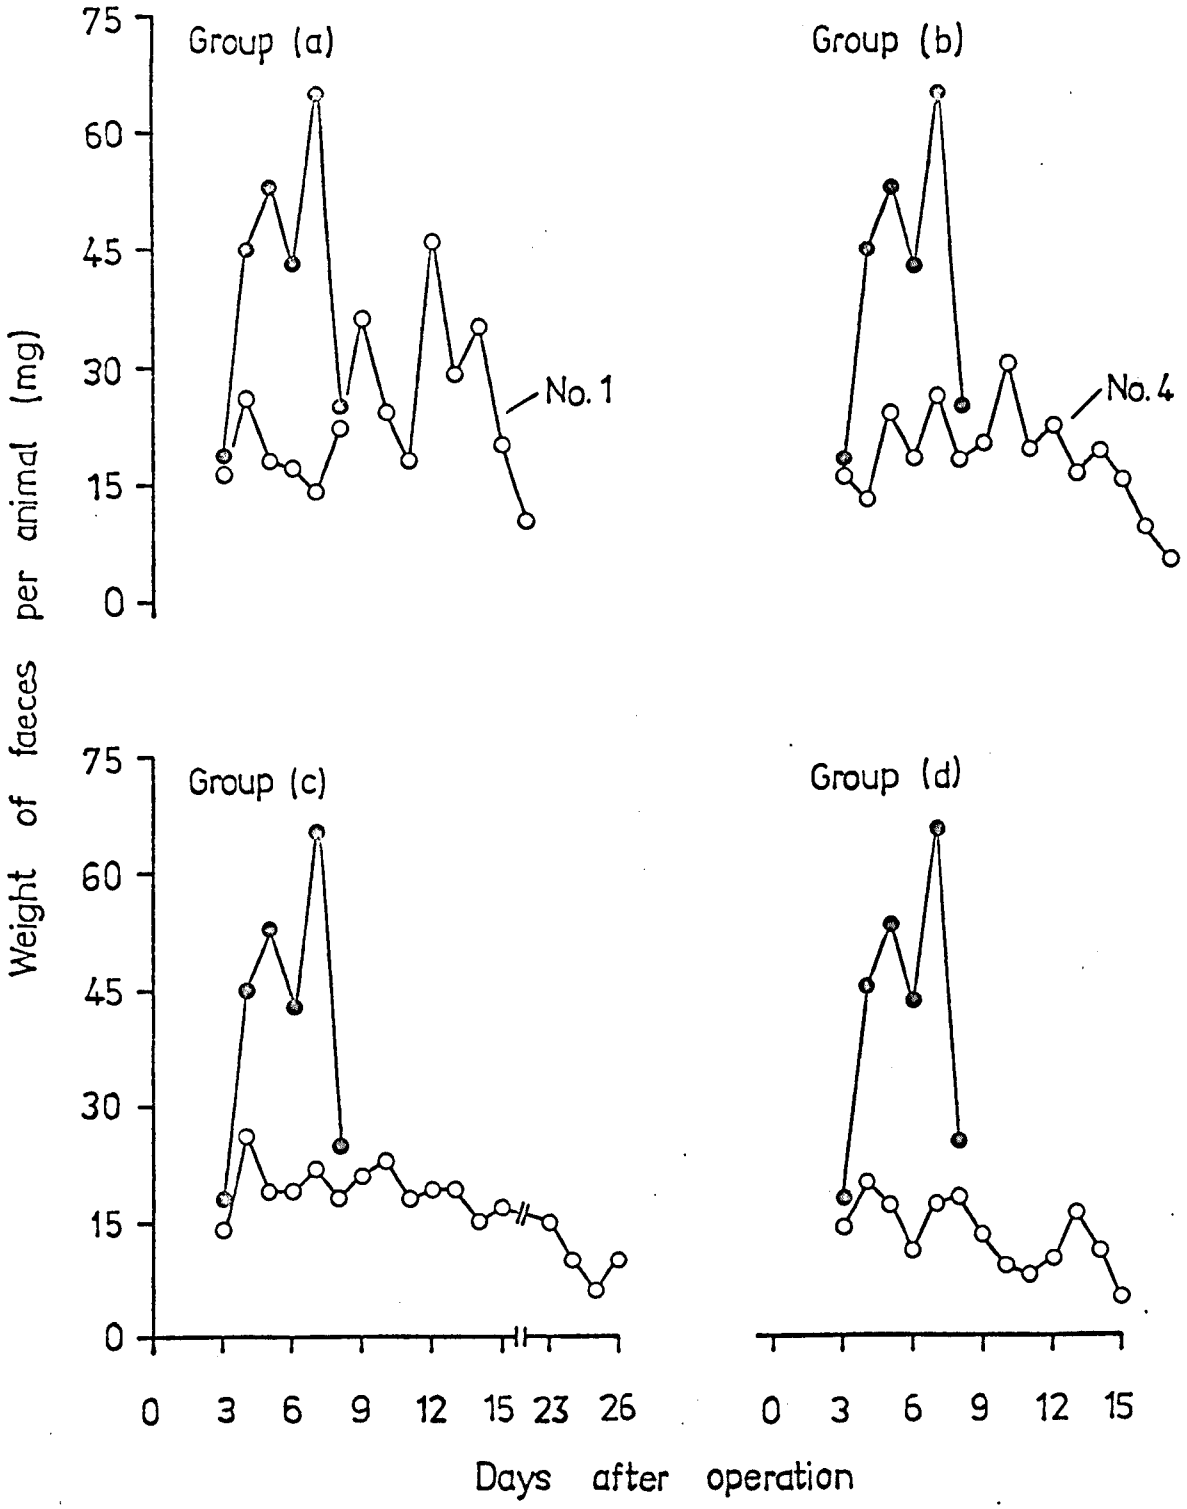

Fig 24. The weight of faeces produced per animal per day following frontal ganglionectomy of fourth instar females. o—frontal ganglionectomized animals, ●— control animals.

developed a new cuticle, and died while trying to moult to fifth instars on Days 12 and 17 respectively (Figs. 21 and 22). Moderate amounts of food were present in the foregut and midgut of both animals at autopsy (Table 23). Less food was present in the hindgut, and air was detected in the rectum of one animal (No. 2). Death was a result of the operated animals being unable to empty the foregut of food prior to swallowing air at ecdysis. The mean daily level of faeces production in both sexes was reduced in comparison to the controls (Table 21). Despite this the peak in faeces production of operated male No. 2 was the same height as the mean control male peaks (Fig. 23).

(b) Reduced growth (50-100% increase in weight) and attempted moulting

One male (No. 5) and two females (Nos. 3 and 4) showed maximum weight increases that were 50-100% above their operation weights. All three developed a new cuticle but failed in their attempts to moult to fifth instars. The growth curves of male No. 5 and female No. 5 are presented in Figs. 21 and 22 and it can be seen that they attempted to moult at weights which were only 11% and 17% respectively above their operation weights. At autopsy the foregut and midgut of group (b) operated animals contained moderate amounts of food which was otherwise absent from the rest of the gut (Table 23). Air was detected in the rectum of two animals (Nos. 3 and 4). Animals in group (b), like those in group (a), died because they were unable to empty the foregut of food at the time of the moult. Daily faeces production

and body weight increase in both sexes were reduced in comparison to group (a) operated animals (Table 21, Figs. 23 and 24).

(c) Reduced growth (50-100% increase in weight) and no attempted moulting

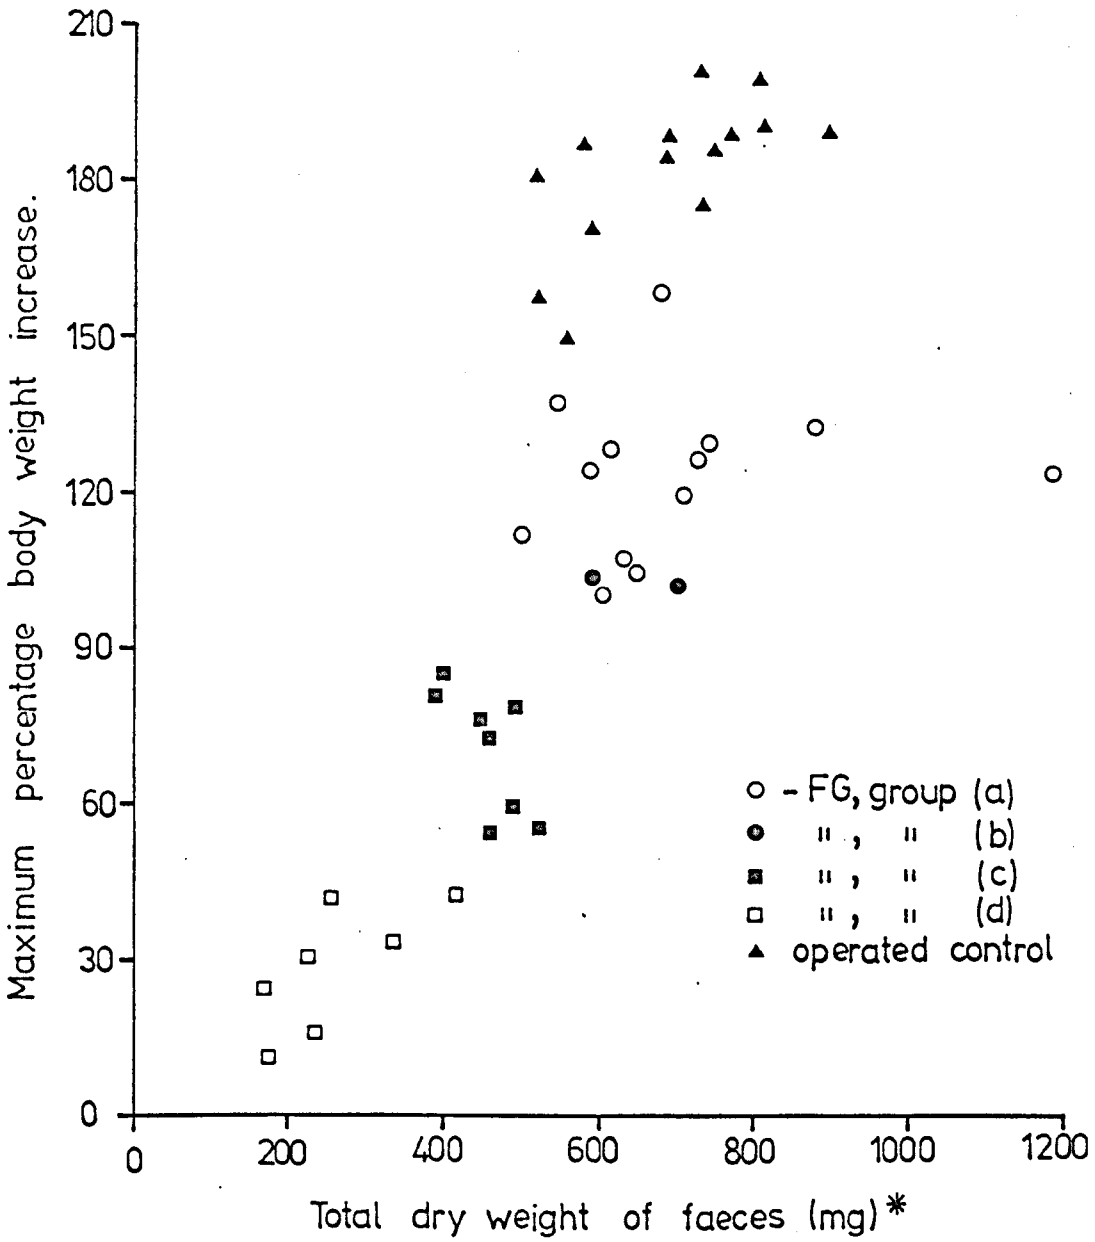
Three males and three females exhibited weight increases similar to those of group (b) animals but failed to develop a new cuticle, even after 26 days (Figs. 21 and 22). At autopsy the foregut of the majority of individuals was found to be packed full of undigested grass (Table 23). Daily faeces production and body weight increase in both sexes were much the same as in group (b) animals (Table 21).

(d) Little or no growth (0-50% increase in weight) and no attempted moulting

Two males and four females maintained an approximately constant weight after removal of the frontal ganglion (Figs. 21 and 22), and failed to develop a new cuticle. The foregut of every individual was found to be distended with undigested food at autopsy (Table 23). A constant low level of faeces production was manifest in animals of group (d) (Figs. 23 and 24) and this was associated with their low weight increases (Table 21). The peak(s) in faeces production witnessed in control and group (a) operated animals was absent in groups (c) and (d) operated animals.

The results in Section III show that frontal ganglionectomy has a variable effect on food passage, growth and cuticle development. The amount of growth taking place after the operation is directly related to the rate at which food leaves the foregut. True growth (minimum twofold increase in body weight) occurs when food passes through the gut unhindered; accumulation of food in the foregut results in little or no growth at all. Fig. 25 illustrates the relationship between the total amount of food passed through the gut (during the instar period in control and group (a) operated animals, and up until the time of death in groups (b), (c) and (d) operated animals) and maximum body weight gain in fifth instar animals of both sexes. It can be seen that group (a) operated animals tend to pass similar quantities of food through the gut to the controls but exhibit lower maximum body weight increases. This suggests that group (a) operated animals convert the ingested food into body tissue less efficiently than the controls. Part of the body weight gain in groups (c) and (d) operated animals of both instars is of course attributable to the accumulated, undigested food present in the foregut of these animals.

Frontal ganglionectomy also has a variable effect on the pattern of faeces production. Thus in group (a) operated animals, where food passes through the gut apparently unhindered, the peak in faeces production is readily distinguishable. On the other hand in groups (c) and (d) operated animals, where food passage out of the crop is restricted, the faeces peak is abolished altogether.



(* produced in the instar period in control and group (a) operated animals, and up until the time of death in groups (b), (c) and (d) operated animals).

FIG 25. The relationship between faeces production and body weight increase in frontal ganglionectomized and control fifth instar animals of both sexes.

The only long-term measurements of food consumption in frontal ganglionectomised locusts are those made by ROOME (1968) in third and fifth instar Locusta nymphs. Food consumption in operated animals of both instars was reduced to one-third to one-quarter that in the controls. The frontal ganglionectomised animals of ROOME maintained an approximately constant weight and displayed distended foreguts at autopsy; they therefore correspond to group (d) operated animals of the present work. From short-term feeding experiments BERNAYS and CHAPMAN (personal communication) found that frontal ganglionectomised fifth instar Locusta males consumed approximately half as much food as the controls during the course of a single meal.

CLARKE and LANGLEY (1963b) and CLARKE and GILLOTT (1965) state that frontal ganglionectomy in third instar Locusta nymphs does not adversely affect food intake and faeces production. Lack of growth after this operation is believed to be caused by a decrease in the activity of the neurosecretory system rather than be a lack of food. However, in the present study those operated animals failing to grow exhibit a correspondingly low level of faeces production, there being no examples of high faeces production and no growth. In contrast to the above authors HIGHNAM et al. (1966) report that removal of the frontal ganglion in immature adult female Schistocerca inhibits emptying of the foregut and consequently greatly reduces faeces production (HILL et al., 1966). Such operated animals are classed as 'semi-starved', and groups (c) and (d) animals of the present study fit into this category.

The frontal ganglionectomised fourth instar Locusta females of ROOME (1968) are divided into two groups according to their survival and growth responses: (1) 'short-lived' animals that survive for no longer than 10 days and exhibit a rapidly declining level of faeces production, which is associated with low weight increase and a distended crop at autopsy; (2) 'long-lived' animals that survive for longer than 10 days and show a relatively steady daily level of faeces production, which is more than double that of the short-lived animals but considerably less than that of the controls. By their growth responses, the long-lived animals of ROOME fit into groups (b), (c) and (d) (fourth instars) of the present work. Frontal ganglionectomy in Melanoplus (DOGRA and EWEN, 1971) has little or no effect upon food consumption, but severely restricts food passage out of the foregut. In consequence the crop becomes greatly distended and in a few individuals it actually bursts (GILLOTT et al., 1970).

The effects of frontal ganglionectomy on weight increase, new cuticle formation, and moulting behaviour are summarized in Table 24.

CLARKE and LANGLEY (1963c) removed the frontal ganglion from third instar nymphs at 0 hr, 12 hr, 24 hr, 33 hr, 72 hr and 96 hr after ecdysis. The 96 hr operated animals exhibited a steady weight loss until death. All the other operated animals maintained a constant weight and therefore correspond to group (d) operated animals of the present work. A new cuticle was developed by all of the 72 hr and 96 hr, and by a

TABLE 24 Weight increase, new cuticle formation and moulting behaviour in frontal ganglionectomised fourth and fifth instar Locusta nymphs

Instar	No. operated	No. surviving beyond Day 10	% animals surviving beyond Day 10 showing:				
			Weight increase (%)			New cuticle formation	Attempted moulting
			0-50	50-100	100		
5th	38	30	23	27	50	43	43
4th	30	17	35	53	12	29	29

few of the 33 hr operated animals. The 96 hr operated animals managed to split the old cuticle, but their attempts at moulting to the next stage proved unsuccessful. CLARKE and LANGLEY deduced that wound adhesions were responsible for this effect but a more likely explanation is failure of the operated animals first to empty the gut of food and second to swallow air.

ROOME (1968) removed the frontal ganglion from fourth instar Locusta females that were aged 8 hr ± 8 hr at the time of the operation. Of the nine animals surviving for longer than 10 days (long-lived), six exhibited weight increases similar to those of animals in groups (b) and (c) of the present work, while three showed weight increases which fit them into group (d). It is probable that had they not been sacrificed on Day 14 several of these long-lived animals would have increased their body weights sufficiently to fit into group (a). A new cuticle was developed by two of ROOME's long-lived animals.

Growth and new cuticle development can, therefore, still occur in the absence of the frontal ganglion, but successful moulting is blocked at all times.

SECTION IV

THE MORPHOLOGY OF THE ANTERIOR STOMATOGASTRIC NERVOUS SYSTEM

The earliest mention of the stomatogastric nervous system in Locusta is by BRANDT (1831) (as quoted in DUMORTIER, 1969). ALBRECHT (1953) provides the first detailed account of its structure and relationship with the brain and gut. His work has subsequently been extended by the studies of LANGLEY (1962), GRENVILLE (1962), CLARKE and LANGLEY (1963b, c), STRONG (1966) and ROOME (1968). The most comprehensive account of any orthopteran stomatogastric nervous system is that by WILLEY (1961) for Periplaneta. KHATTER (1968) describes at some length this system in another orthopteran, Schizodactylus monstrosus, while CAZAL (1948) frequently mentions the stomatogastric nervous system in his review of the arrangement of the retrocerebral glands in a wide variety of insect orders, including the Orthoptera.

The continued growth of some animals after removal of the frontal ganglion, as reported in Sections II and III, implies that sensory impulses produced by distension of the foregut must be reaching the brain and/or corpora cardiaca along

pathways other than those involving the frontal ganglion. An alternative route is suggested by STRONG (1966) and involves fine nerves leaving the surface of the pharynx ⟶ hypocerebral ganglion ⟶ nervi corporis cardiaci interni. Further routes are sought during the present investigation into the morphology of the anterior stomatogastric nervous system in Locusta. This part of the system includes the frontal connectives, frontal ganglion, recurrent nerve, hypocerebral ganglion and the various fine nerves connected to the frontal and hypocerebral ganglia. The structure and arrangement of the ingluvial ganglia, inner and outer oesophageal nerves and the fine nerves attached to ingluvial ganglia has been considered in Locusta by GRENVILLE (1962) and STRONG (1966), and in Schistocerca by DANDO et al. (1968).

Newly moulted fifth instar Locusta nymphs were starved for several days to remove fat tissue from the vicinity of the nerves. The locusts were then subjected to intra-vitam injection of reduced methylene blue according to the method of STARK et al. (1969). The following account is based on the results of some thirty dissections of injected specimens.

Muscles innervated by nerves of the anterior stomatogastric nervous system

ALBRECHT (1953) describes in detail the arrangement of the head muscles in Locusta and only a few additional observations are necessary here.

Situated just below the base of each antenna and adjacent to the frontal carina are two oval patches of cuticle which differ slightly in colour and pigmentation from the rest of the frons cuticle (Fig. 26). The lower patch, light brown in colour, is the external manifestation of the points of origin of four muscles: the anterior retractor of the labrum, the posterior retractor of the labrum, the retractor of the mouth angle and the second dorsal dilator of the pharynx (Figs. 27 and 28). The upper patch, yellow in colour, overlies the antennal ampulla (UVAROV, 1966). A broad, thin transverse band of muscle runs between the two antennal ampullae. Another band of muscle fans out ventrally from each ampulla and, passing outside the second dorsal dilator muscle of the pharynx and inside a large frontal air sac, inserts into the tunica muscularis close to the point of insertion of the first lateral dilator muscle of the pharynx (Fig. 29). In several orthopteran species (PAWLOWA, 1895 a, b) the walls of the aorta fuse with the transverse and vertical muscles of the ampullae. This also appears to be the case in Locusta.

Frontal connectives and their branches

The frontal ganglion lies in the midline of the foregut between the second dorsal dilator muscles of the pharynx. Two frontal connectives leave its anterolateral margins and pass back on each side of the gut to the tritocerebral lobes of the brain. Just before entering the tritocerebrum each frontal connective fuses with the labral nerve on that side to form a short labrofrontal nerve root.

Fine nerves have been observed leaving the frontal connectives in Gryllotalpa gryllotalpa, Bacteria ferula and Blatta orientalis (BRANDT, 1835), Pachytylus migratorius, Stenobothrus bicolor and Forficula auricularia (PAWLOWA, 1895), Dixippus morosus (NYST, 1942), Naucoris cimicoides (CAZAL, 1948), Periplaneta (WILLEY, 1961), Blaberus craniifer (WILLEY, 1961), Schizodactylus (KHATTER, 1968) and Blabera fusca (BROUSSE-GAURY, 1971). As far as Locusta is concerned, ROOME (1968) observed fine nerves branching from the frontal connectives but did not trace them for any distance.

Usually three fine nerves are given off from each frontal connective in the region where this nerve loops back towards the tritocerebrum (Fig. 30, Plate 54). The first frontal connective nerve branch (FCN_1) runs forward to the second anterior dilator muscle of the cibarium and to the tunica

muscularis of the clypeal epipharynx and the pharynx proper. Sensory cell bodies, whose axons connect with the FCN_1, can be detected lying on the tunica muscularis and occasionally on the dilator muscles. Motor nerve nedings of the FCN_1 branches are also evident in these muscles (Plate 56). A branch of the FCN_1 passes back under the frontal connective, branches to the first dorsal dilator muscle of the pharynx and then links up with the anterior pharyngeal nerve (Fig. 30).

The second frontal connective nerve branch (FCN_2) passes anteriorly and branches extensively to supply the following muscles: posterior retractor of the labrum, retractor of the mouth angle, anterior retractor of the labrum, first and second anterior dilators of the cibarium, compressor of the labrum and the tunica muscularis of the clypeal epipharynx (Fig. 30, Plate 54). Sensory cell bodies, whose axons connect with the FCN_2, are located on the tunica muscularis and occasionally on the dilator muscles while motor endings of the FCN_2 branches are common in both muscle regions. The main FCN_2 nerve branch may unite with its opposite number before innervating the compressor of the labrum or the two may be joined by 'link' nerves. The FCN_2 is probably homologous to the 'N_2' of WILLEY (1961).

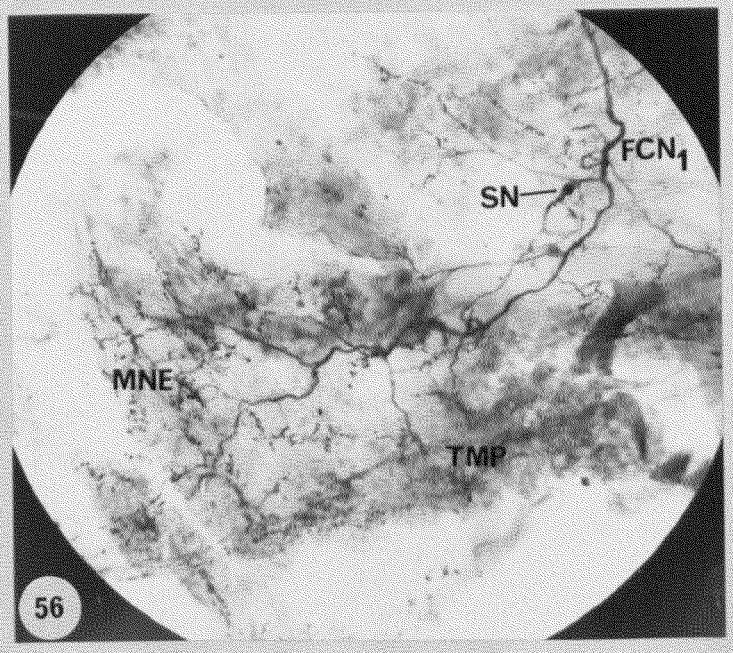
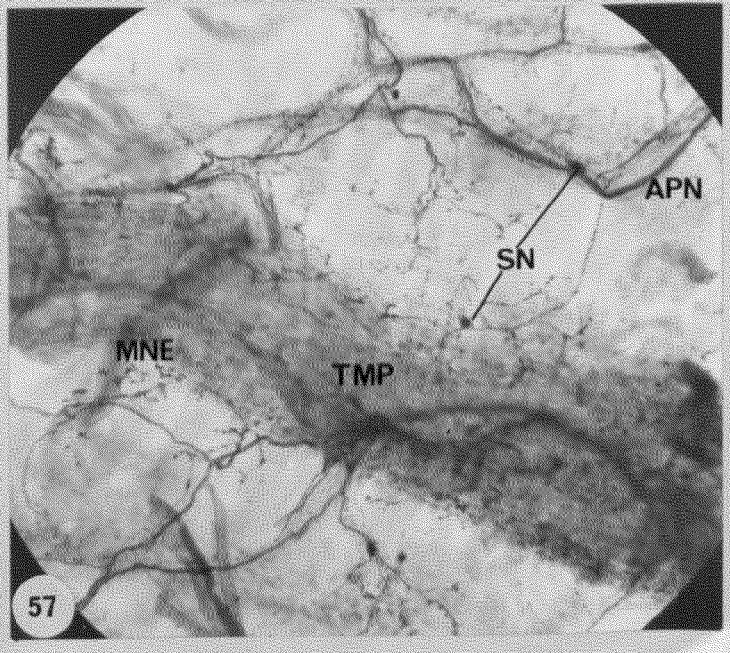
PLATES 56, 57





The third frontal connective nerve branch (FCN_3) divides to form an anterior branch which innervates the posterior retractor of the labrum and a posterior branch which innervates the rectractor of the mouth angle. This nerve is probably homologous to the 'N_1' of WILLEY.

While the FCN_3 and FCN_2 nearly always arise as separate branches of the frontal connective, the FCN_1 may branch from the FCN_2 instead of from the frontal connective.

Several other fine nerves were observed leaving the frontal connectives but could not be regularly identified in every dissected specimen. Thus, on one side only, a nerve occasionally leaves the frontal connective just before it fuses with the labral nerve (Fig. 30, Plate 54). The nerve branch divides into two, one half connecting with the FCN_2 and the other extending to the inner epithelium of the clypeus. WILLEY (1961) for Blaberus and KHATTER (1968) for Schizodactylus figure a nerve leaving the frontal connective just before it fuses with the labral nerve. In Schizodactylus the nerve branch supplies the pharyngeal muscles.

One or both frontal connectives occasionally branch just before they enter the frontal ganglion. The branch may re-enter the frontal connective or join the FCN_1 (Fig. 30).

The frontal connective and labral nerve are often connected by very fine 'link' nerves (Fig. 30).

Anterior, median and posterior pharyngeal nerves

The anterior and posterior pharyngeal nerves were first described in Locusta by CLARKE and LANGLEY (1963 b, c). A third pair of fine nerves, the median pharyngeal nerves, are given off from the frontal ganglion between the anterior and posterior pairs (ROOME, 1968). Fine nerves leaving the frontal ganglion between the frontal connectives and the recurrent nerve are also described for Polyzosteria nitida, Gryllus domesticus, Stenobothrus and Forficula (PAWLOWA, 1895), Hierodula bioculata and Gryllotalpa vulgaris (BORDAS, 1900), Oryctes nasicornis (PAWLOWA, 1895; ORLOV, 1924), Carausius morosus (DUPONT-RAABE, 1957), Periplaneta (WILLEY, 1961; DAVEY and TREHERNE, 1963), Schizodactylus (KHATTER, 1968) and Blabera (BROUSSE-GAURY, 1971).

The anterior pharyngeal nerves (APNs) emerge from the anterolateral borders of the frontal ganglion, just behind the origin of the frontal connectives. They innervate the first dorsal and lateral dilator muscles of the pharynx, the rectractor muscles of the mouth angle and the tunica muscularis of the pharynx (Fig. 30). Axons of sensory cell bodies found lying on the tunica muscularis and occasionally on the dilator muscles connect with the APNs. Motor nerve endings of the fine branches of the APNs are also apparent in these muscles (Plate 57).

The median pharyngeal nerves (MPNs) either emerge separately from the frontal ganglion, just posterior to the APNs, or arise as branches of the APNs. They innervate the second dorsal dilator muscles of the pharynx (Fig. 30).

The site of origin of the posterior pharyngeal nerves (PPNs) is, in comparison to that of the APNs, unpredictable. Thus, both PPNs may arise from the frontal ganglion, both from the recurrent nerve or one from the frontal ganglion and one from the recurrent nerve. The PPNs branch profusely over the surface of the pharynx and oesophagus to innervate the second and third dorsal dilator muscles of the pharynx, the second lateral dilator muscles of the pharynx, the first, second and third ventral dilator muscles of the pharynx, the thin vertical muscle sheets associated with the antennal ampullae and the tunica muscularis of the pharynx (posterior region) and oesophagus. The PPNs also connect with branches of the APNs and MPNs, branches of the recurrent nerve, branches of the hypocerebral ganglion, the nervi corporis cardiaci III (NCC III), the corpora cardiaca, the nervi corporis allati I and II (NCA I and II) and also the aorta (Fig. 31, Plate 55). Sensory cell bodies whose axons connect with the PPNs can be detected lying on the surface of the tunica muscularis and occasionally on the dilator muscles. Motor nerve endings of the fine branches of the PPNs are also apparent in these muscles (Plate 58).

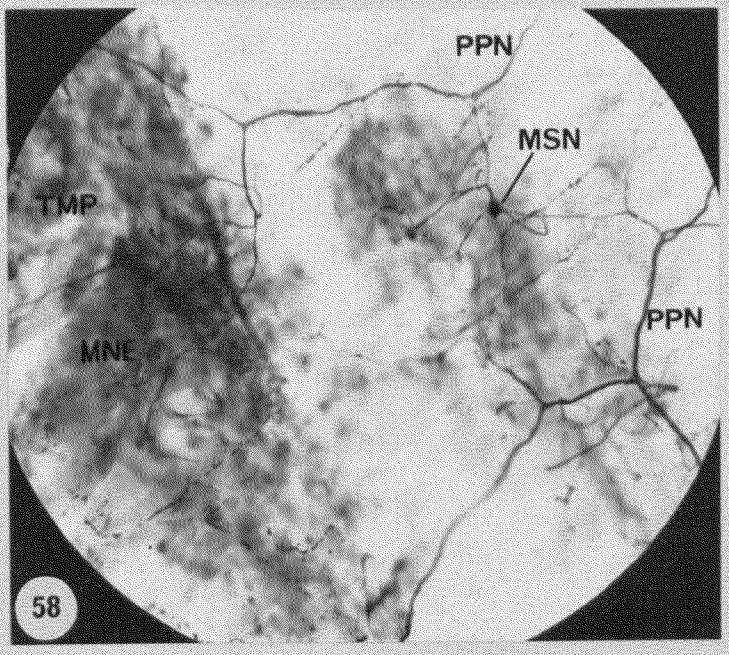
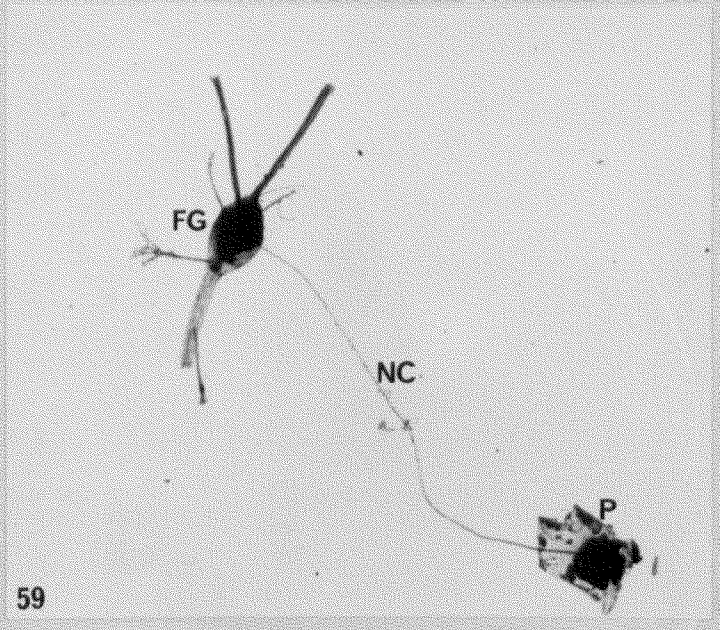
PLATES 58, 59





LANGLEY (1962) and CLARKE and LANGLEY (1963b) describe a nerve leaving the NCA II and branching to the ventral dilator muscles of the pharynx, the muscles of the ventral head apodeme and the tritocerebrum. RAABE (1963b, 1964), also for Locusta, depicts a nerve branching from the NCA II to the ventral dilator muscles of the pharynx and shows the NCC III branching to the corpora allata and corpora cardiaca. She adds that in Locusta, Aeschna grandis, Carausius and Gryllus the NCC III branches to the dilator muscles of the pharynx and in the latter three insects it also connects with the recurrent nerve. From the present study it is clear that the nerve CLARKE and LANGLEY observed branching to the tritocerebrum is almost certainly the NCC III and the branch of the NCC III said by RAABE to innervate the dilator muscles of the pharynx is in fact part of the PPN. In Carausius (DUPONT-RAABE, 1957) the PPN supplies the dilator muscles of the pharynx and also joins the NCC III, the combined nerve root then entering the corpora cardiaca. The equivalent of the PPN in Periplaneta, 'N_5' of WILLEY (1961), is reported by this author only to innervate the tunica muscularis of the pharynx, there being no obvious link up with the NCC III. According to DAVEY and TREHERNE (1963) the 'N ' in this insect terminates in a sensory organ which they believe to be an osmoreceptor. These authors also record a single median nerve passing posteriorly from

the ventral surface of the frontal ganglion to the muscular coat of the pharynx; no such nerve exists in Locusta.

Nervus connectivus

A slender median nerve, the nervus connectivus, arises from the mid-dorsal surface of the frontal ganglion. It passes back through the transverse muscle band connecting the antennal ampullae and enters the protocerebrum (Plate 59). The nervus connectivus was first named by BALDUS (1924) in the dragonfly Aeschna, although PAWLOWA (1895) had previously figured the nerve in various Orthoptera, labelling it 'n_3'. CAZAL (1948) reviews the occurrence of this nerve throughout the Insecta and finds it to be a characteristic feature of the more primitive orders. According to WILLEY (1961) the nervus connectivus is found in all orthopteroids except the Saltatoria but this nerve has not previously been described in Locusta migratoria migratorioides. In Periplaneta (WILLEY, 1961) the nervus connectivus is composed of two large axons which belong to a pair of large unipolar cell bodies situated on the median anterior face of the protocerebrum. The nervus connectivus does not branch and its function remains undetermined.

Other fine nerves leaving the frontal ganglion

In many insects a single median nerve, the frontal nerve (IMMS, 1957), emerges from the anterior margin of the frontal ganglion and runs forward over the dorsal surface of the pharynx and cibarium innervating various muscles in these regions. CLARKE and LANGLEY (1963c) provide a list of insects in which the frontal nerve has been detected. To it may be added the following species: Hyloicus ligustri (NEWPORT, 1832), Bombyx mori (BLANC, 1890), Forficula (PAWLOWA, 1895a), eight different orthopteran species (BORDAS, 1900), Grylloblatta campodiciformes (NESBITT, 1956), Dendroctonus pseudotsugae (ATKINS and CHAPMAN, 1957), Dytiscus marginalis (RAABE, 1963 a), Schizodactylus (KHATTER, 1968) and Actias selene (ROOME, 1968). A single median nerve is also observed in Locusta, though not in every dissected specimen. When present it seems to connect with the FCN_1 (Fig. 30, Plate 54) or the frontal connective. An alternative arrangement is apparent in Plates 60a, b where a multiterminal neurone is seen to be closely associated with the FCN_2. The dedritic processes of the neurone run on and in this nerve while the axon enters the frontal ganglion midway between the points of origin of the frontal connectives. Multiterminal neurones have also been identified on major nerves in Carausius (FINLAYSON and OSBORNE, 1968). The

muscles innervated by the frontal nerve in, for example, Schizodactylus are, in Locusta, supplied by the FCN_1 and FCN_2.

Two fine nerves leave the frontal ganglion between the frontal connectives and run forward over the surface of the gut in the Odonata (BRANDT, 1838), Pachytylus, Polyzosteria and Oryctes (PAWLOWA, 1895), Dixippus (NYST, 1942) and Forficula and Sialis lutaria (CAZAL, 1948). In Gryllus (PAWLOWA, 1895) and Gryllotalpa (BORDAS, 1900) three fine nerves arise just in front of the points of origin of the frontal connectives. In Periplaneta (WILLEY, 1961) the number is four ('N_3' and 'N_4') while in Schizodactylus (KHATTER, 1968) it is six (not including the frontal nerve).

Plate 61a shows a frontal ganglion with all its nerve connections intact. The single anteriorly directed median nerve is absent and the nervus connectivus has been cut near its base. The extremely fine nerves are probably axons of sensory cell bodies occasionally found lying on fat body tissue and against the frontal air sacs. FINLAYSON and OSBORNE (1968) describe a fat body neurone in Carausius whose axon enters a nerve connected to the second abdominal ganglion; its function is unknown.

Recurrent nerve and its branches

The frontal ganglion narrows posteriorly into the recurrent nerve trunk which passes back along the mid-dorsal line of the gut to the hypocerebral ganglion. Several (the number is variable) fine nerves leave the recurrent nerve and link up with the branches of the PPNs (Plate 61b). Some of these branches then innervate the tunica muscularis of the pharynx and oesophagus (Fig. 31). In Stenobothrus (PAWLOWA, 1895a), Oryctes (ORLOV, 1924), Periplaneta (WILLEY, 1961), Schizodactylus (KHATTER, 1968) and Actias (ROOME, 1968) branches of the recurrent nerve innervate the muscle coat of the pharynx and oesophagus. In Dytiscus (RAABE, 1963 b) a pair of fine nerves emerge from the recurrent nerve and supply the lateral dilator muscles of the pharynx while in Gryllus, Aeschna and Carausius (RAABE, 1963 b) branches of the recurrent nerve connect with the NCC III. A fine nerve branch, containing two bipolar neurones, arises from the ventral surface of the recurrent nerve in Phormia (GELPERIN, 1967) and connects with the anterior region of the foregut. From electrophysiological experiments it is concluded that the two neurones are stretch receptors.

Nerves connected to the hypocerebral ganglion

The hypocerebral ganglion lies on the dorsal surface of the oesophagus, just behind the brain and immediately underneath the anterior unpaired lobe of the corpora cardiaca. Its neuropile is continuous with the recurrent nerve, the inner and outer oesophageal nerves, branches of the NCC I and small nerves to the pharynx (STRONG, 1966). The small or fine nerves usually link up with branches of the PPNs before innervating the muscle coat of the oesophagus (Fig. 31, Plate 55). Fine nerves leaving the hypocerebral ganglion and passing to the surface of the oesophagus are also described for Dixippus (PFLUGFELDER, 1937; NYST, 1942), Periplaneta (WILLEY, 1961), Schizodactylus (KHATTER, 1968), and Oryctes, where they connect with branches of the recurrent nerve and PPNs (ORLOV, 1924). In Grylloblatta (NESBITT, 1956) fibres from the hypocerebral ganglion innervate the aorta.

The above neuromorphological study has shown that the necessary sensory and motor nerve elements are present in the pharynx and oesophagus for the co-ordinated control of muscular activity in these regions. On the basis of work carried out in other insects by ZAWARZIN (1916) and DANDO et al. (1968), the multipolar or multiterminal (FINLAYSON,

1968) neurones found lying on the surface of the pharynx and oesophagus in Locusta can be classed as Type II sensory cells. CLARKE and LANGLEY (1963c) and PLOTNIKOVA (1967) go further and suggest that these cells function as stretch receptors, although this still awaits electrophysiological confirmation.

In the light of the present investigation the account by LANGLEY (1962) and CLARKE and LANGLEY (1963c) on the distribution of the PPNs is now seen to be inaccurate. The region of the pharynx described by these authors as being innervated by the PPNs is, in fact, supplied by the APNs and FCN_1, with the PPNs supplying that region of the foregut which lies posterior to the frontal ganglion. The PPNs branch extensively and link the stomatogastric nervous system with the neuroendocrine system at the level of the corpora cardiaca and also at the level of the NCA II.

The distribution of the fine nerves of the anterior stomatogastric nervous system is such that even after the removal of the frontal ganglion several nervous pathways are open to the insect for the conveyance of sensory information from the foregut to the neuroendocrine system. The FCN_1, FCN_2, APN and PPN are mixed nerves. In Section V the ultrastructure of one of these, the PPN, is investigated and its axon diameters measured.

SECTION V

AN ELECTRON MICROSCOPICAL EXAMINATION OF THE HYPOCEREBRAL GANGLION, INGLUVIAL GANGLION, FRONTAL CONNECTIVE, RECURRENT NERVE AND POSTERIOR PHARYNGEAL NERVE

Neurosecretory material cannot be detected in the intrinsic neurones of the stomatogastric nervous system in Locusta at the light level (GRENVILLE, 1962; LANGLEY, 1962; CLARKE and LANGLEY, 1963 c; STRONG, 1966). STRONG did, however, observe several neurosecretory axons from the nervi corporis cardiaci interni enter the neuropile of the hypocerebral ganglion and leave in the inner and outer oesophageal nerves. These nerves in Melanoplus sanguipipes also contain neurosecretory fibres from the nervi corporis cardiaci interni (DOGRA and EWEN, 1970). The only successful light microscopical demonstration of intrinsic neuroglandular cells in the stomatogastric nervous system in any insect is by VAN DER KLOOT (1960) for the frontal ganglion of Bombyx mori.

A quite different picture is manifest at the ultrastructural level. ANSTEE (1968) found the perikarya of the frontal ganglion in Locusta to be actively engaged in the elaboration of neurosecretory granules which he also detected

in many of the axons within the neuropile of this ganglion. His observations were confirmed by CAZAL et al. (1971) who in addition discovered neurosecretory material in the hypocerebral ganglion of this insect. CHANUSSOT et al. (1969) provide pictorial evidence of the existence of neurosecretion in the ingluvial ganglion of Blabera craniifer and describe its presence in this ganglion in Schistocerca.

ANSTEE (1968) inspected a limited number of thin sections of the recurrent nerve but was unable to detect neurosecretory material in any of its axons. The recurrent nerve runs between the frontal ganglion and the hypocerebral ganglion and since both of these ganglia actively manufacture neurosecretion its non-appearance in the recurrent nerve is somewhat surprising. The recurrent nerve therefore merits further attention.

In this section the fine structure of the frontal ganglion, as described by ANSTEE (1968) and CAZAL et al. (1971), is compared with that of the hypocerebral and ingluvial ganglia, the account by CAZAL et al. of ultrastructure of the hypocerebral ganglion being of sufficient brevity to justify this further investigation. The frontal connective, recurrent nerve and posterior pharyngeal nerve, all of which were cut during various experiments described in Sections I and II, are also examined at the ultrastructural level. The

required tissues in mid-fourth instar nymphs and 10-day-old adults were fixed and processed for electron microscopy according to the methods described in Chapter II. For each tissue sections were taken of six animals and the results presented below are representative, in each case, of over one hundred cell profiles. Plates 75, 77, 81, 85 and 87 are of fourth instar animals while the remaining plates in this section are of adults. Since nerve axons and neurosecretory granules are rarely perfectly circular in transverse section the figure given for 'diameter' is the mean of the two diameters (WIGGLESWORTH, 1959).

Hypocerebral Ganglion

The hypocerebral ganglion is invested with a nerve sheath comprising an outer acellular layer, the neural lamella, and an inner cellular layer, the perineurium. Concentrated mainly round the dorsal and dorso-lateral aspects of the medullary neuropile are the cortical neurone cell bodies or perikarya. The sub-perineurial glial system ensheaths the neuronal perikarya and extends as narrow processes into the neuropile.

The nerve sheath

The structure of the neural lamella resembles that of its counterpart in the metathoracic ganglion (ASHHURST and CHAPMAN, 1961). It therefore consists of a meshwork of collagen-like fibrils set in an amorphous background substance which is frequently penetrated by tracheoles. According to ASHHURST (1959) the background substance is a neutral mucopolysaccharide.

The fine structure of insect perineurial cells has been described by HESS (1958), ASHHURST and CHAPMAN (1961), TRUJILLO-CENOZ (1962), SMITH and TREHERNE (1963), MADDRELL and TREHERNE (1967) and SMITH (1967). In Locusta the distinctive features of the perineurial cells are the abundant rod-shaped mitochondria and the large intercellular spaces which are produced when adjacent pairs of intercellular membranes diverge widely from one another (Plate 62). The intercellular clefts, which open directly under the neural lamella, are held together at their inner ends by septate desmosomes. Also present in the cytoplasm are scattered Golgi complexes, profiles of rough endoplasmic reticulum, free ribosomes, sparsely distributed clusters of glycogen granules and microtubules. The perineurium nucleus is sausage-shaped and contains dense clumps of chromatin material.

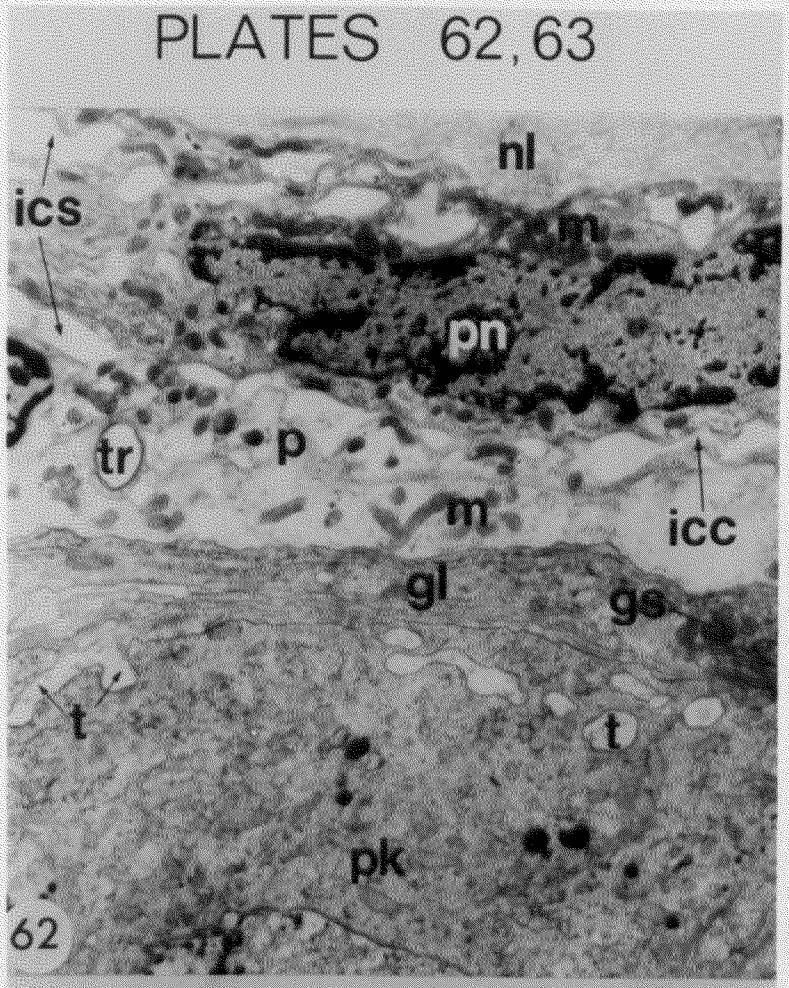
PLATE 62. Electron micrograph of the cortical region of the hypocerebral ganglion. At the top of the field lies the neural lamella (nl) and below this the perineurium (p). The characteristic intercellular clefts (icc) between adjacent perineurial cells periodically diverge to form large intercellular spaces (ics). Multiple closely packed sheets of glia (gl) separate the perineurium from the perikaryon (pk). The innermost of these sheets invaginates the perikaryal nucleus (pn), mitochondria (m), tracheole (tr) and gliosome (gs).

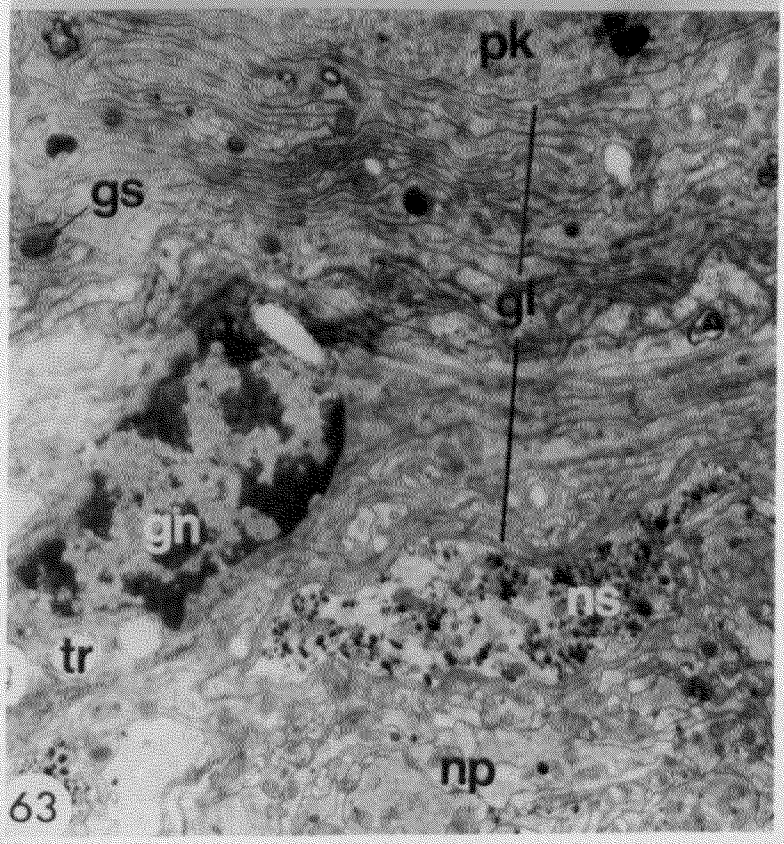
Magnification x 9,400.

PLATE 63. A section taken through the edge of the hypocerebral ganglion neuropile. Numerous stacked leaflets of glial cells (gl) separate the perikaryon (pk) from the neuropile (np). The glial cytoplasm contains a glial nucleus (gn), tracheoles (tr) and a gliosome (gs). Note the large neurosecretory axon (ns) in the neuropile.

Magnification x 9,400.

PLATES 62, 63





The neuroglia

The structure and function of the glial cell system in insects has been reviewed by SMITH and TREHERNE (1963), SMITH (1967), TREHERNE (1967) and TREHERNE and MORETON (1970). In the hypocerebral ganglion the attenuated cytoplasmic processes of the glial cells form concentric folds round the neurone cell bodies and the innermost of these glial sheets penetrates the peripheral cytoplasm of the perikaryon to form characteristic invaginated 'glial fingers' (Plate 62). Within the glial cytoplasm may be found profiles of rough endoplasmic reticulum, free ribosomes, scattered Golgi complexes, microtubules, glycogen granules and membrane-delimited dense bodies or gliosomes. In Melanoplus differentialis the gliosomes contain acid phosphatase and are therefore equivalent to lysosomes (LANE, 1968). Mitochondria are also present in the glioplasm but are fewer in number compared to the perineurium. The glial nuclei, like those of the perineurial cells, contain dense clumps of chromatin material, particularly in the vicinity of the nuclear envelope, and a prominent nucleolus. They occasionally migrate from their more normal position beneath the perineurium and come to lie between the perikarya and the edge of the neuropile.

(Plate 63). Multiple stacks of narrow glial leaflets separate the perikaryal and neuropilar regions from one another.

Glial cytoplasm is poorly represented in the neuropile, though occasionally narrow glial elements can be detected interposed between the axon profiles (Plate 65).

The perikarya

The cortical perikarya are made conspicuous by their large, centrally positioned, ovoid or spheroid nuclei. The inner nuclear membrane is more than twice the thickness of the outer membrane (Plate 64), an observation also recorded for nuclei of the corpus cardiacum neurosecretory cells in Calliphora (NORMANN, 1965) and for perikaryal nuclei of the pars intercerebralis in Calliphora (BLOCH et al., 1966) and Locusta (ANSTEE, 1968). The nuclear sap contains a prominent nucleolus, dense clumps of chromatin material and scattered dense spheroid granules, ca. 90 nm in diameter (Plate 64). Granules of similar size, shape and electron density were observed by NORMANN (1965) in Calliphora in the perikaryal nuclei of the hypocerebral ganglion and in nuclei of the corpus cardiacum neurosecretory cells, where they occur in association with chromosomes. Mitochondria are plentiful and evenly distributed throughout the cytoplasm. The numerous randomly distributed profiles of the endoplasmic reticulum

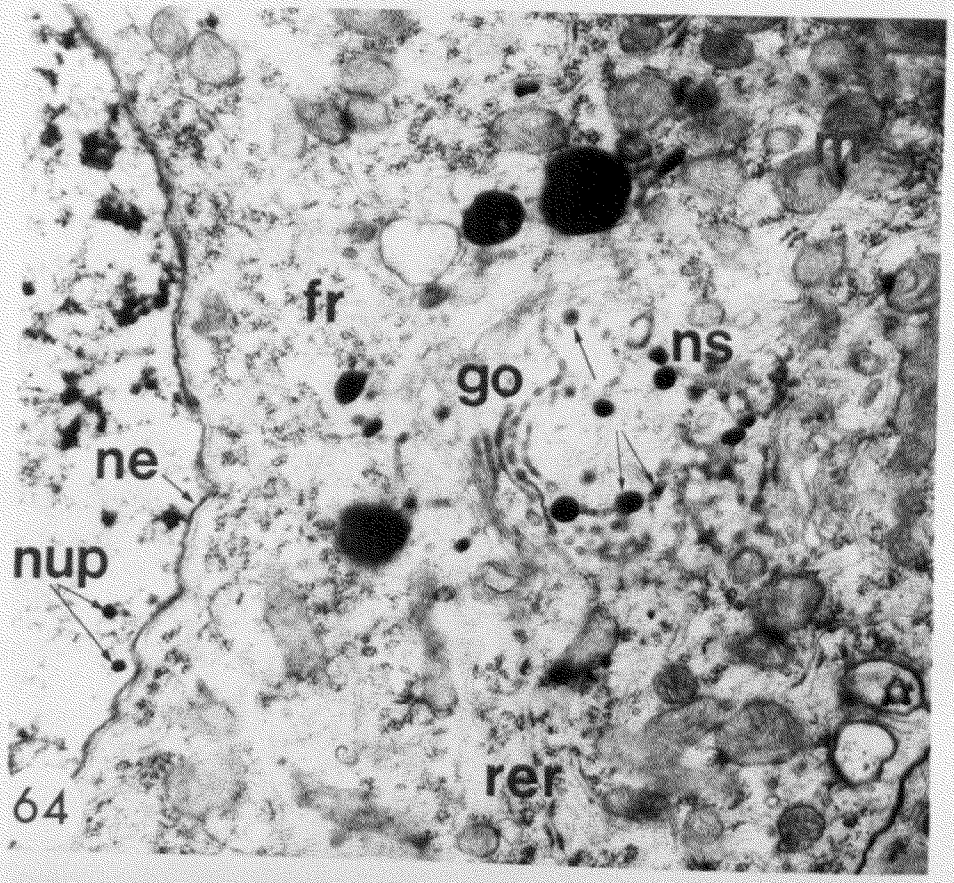
PLATE 64. Electron micrograph of part of a neurosecretory neurone of the hypocerebral ganglion. The Golgi complex (go) is actively manufacturing electron-opaque granules of neurosecretion (ns), some of which are in the process of being pinched off from the periphery (arrows). Profiles of rough endoplasmic reticulum (rer), mitochondria (m) and free ribosomes (fr) are frequently encountered in the perikaryal cytoplasm. Note the nuclear envelope with its thick inner and thin outer walls, and nuclear particles (np) in the nuclear sap.

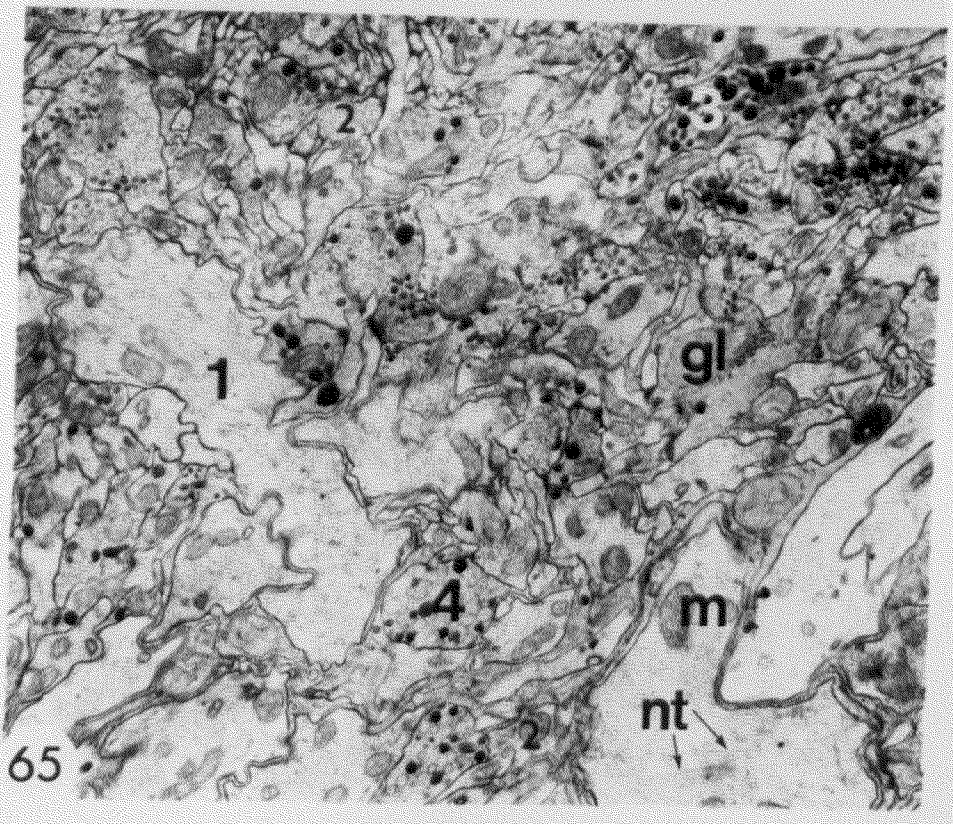
Magnification x 32,000.

PLATE 65. A survey field of the hypocerebral ganglion neuropile. Note the presence of four different axon types: 1 - containing mitochondria (m) and neurotubules (nt) but devoid of neurosecretory material; 2 - containing synaptic vesicles; 3 - containing electron-opaque neurosecretory granules only; 4 - containing electron-opaque and electron-lucent neurosecretory granules. Glial cytoplasm (gl).

Magnification x 15,000.

PLATES 64, 65





appear in the form of flattened membrane-limited cisternae of varying length and undulation to which are attached many ribosomes. Free ribosomes, which are sometimes aggregated into clusters, occur in abundance.

The Golgi apparatus is of special interest since it actively participates in the manufacture of neurosecretory granules, an observation first made by SCHARRER and BROWN (1961) in Lumbricus. This association between the Golgi complex and neurosecretion has since been described in many insect species (WILLEY and CHAPMAN, 1962; SCHARRER, 1963; NORMANN, 1965; BLOCH et al., 1966).

The perikaryal cytoplasm in the hypocerebral ganglion contains many Golgi complexes, a few of which are involved in the manufacture of neurosecretion. Each complex has the typical structure, consisting of stacks of flattened agranular cisternae in close association with vacuoles and vesicles of varying sizes. In favourable sections electron-dense material can be detected within the intracisternal membranes; this material becomes pinched off at the periphery of the cisternae to form membrane-bound granules. The membrane of the newly sequestered granule is usually quite obvious (Plate 64) but it later becomes obscured by the secretion product. Freshly elaborated neurosecretory granules measure 60-100 nm in diameter but electron-opaque granules ranging in diameter

up to a maximum of 500 nm can often be found in close proximity to the Golgi saccules (Plate 64). Electron-opaque neurosecretory granules were the only sort encountered in the neuronal perikarya.

The neuropile

The neuropile of the insect ganglion consists of a complex association of sensory, motor and internunciary axon processes together with gliocyte extensions (SMITH and TREHERNE, 1963). According to the nature of their axoplasmic inclusions bodies, five different 'Axon Types' can be recognised in the neuropile of the hypocerebral ganglion (Plates 65-68):

Axon Type 1 - Axon profiles containing neurotubules, ca. 20 nm in diameter, and mitochondria but no neurosecretory granules.

Axon Type 2 - Axon profiles also devoid of neurosecretion but partially or completely filled with small empty vesicles, ca. 30 nm in diamater; these are probably synaptic vesicles (SMITH and TREHERNE, 1963).

Axon Type 3 - Axon profiles containing electron-opaque neurosecretory granules, 140-200 nm in diamater.

Axon Type 4 - Axon profiles containing a heterogeneous population of neurosecretory granules, ranging in density from

PLATE 66. A section taken through the neuropile of the hypocerebral ganglion. The vast majority of the axons are charged with electron-opaque neurosecretory granules, but here and there can be found scattered type 4 axons containing both electron-opaque and electron-lucent granules.

68

electron-opaque to electron-lucent, and measuring 140-200 nm in diameter.

Axon Type 5 - Axon profiles containing electron-opaque neurosecretory granules, 70-120 nm in diameter, and empty or partially filled vesicles, 50-60 nm in diameter.

Mitochondria and small vesicles, 30-45 nm in diameter, frequent Axon Types 3-5 (Plate 67) but neurotubules are less in evidence (Plate 68).

According to CAZAL et al. (1971) the only type of neurosecretory granule in the neuropile of the hypocerebral ganglion is the electron-opaque variety, ca. 100 nm in diameter. However, the granules in the electron micrograph presented by these authors measure nearer 150 nm in diameter, thus making them equivalent to the electron-opaque granules in Axon Type 3.

Ingluvial Ganglion

In its basic construction the ingluvial ganglion, of which there are two in Locusta, closely resembles the hypocerebral ganglion. Thus the medullary neuropile is almost completely surrounded by the cortical perikarya and both are invested with a nerve sheath consisting of an outer neural lamella and an inner perineurium. The glial cell bodies, the majority of which lie beneath the perineurium, give rise to

narrow cytoplasmic processes which encompass the perikarya and enter, to a limited extent, the neuropile.

The nerve sheath

The nerve sheath and perineurium do not differ significantly in their ultrastructural composition from these layers in the hypocerebral ganglion. Some of their more important features are depicted in Plate 69.

The perikarya

The cytoplasmic organisation of the perikarya mirrors that of the neurone cell bodies in the hypocerebral ganglion. Attention here is focused on the numerous Golgi complexes that are scattered throughout the cell body cytoplasm (Plate 70). Each complex is composed of a stack of flattened membrane-limited agranular cisternae, some of which often exhibit a beaded appearance. The majority of the Golgi bodies are involved in the manufacture of neurosecretory material which collects in a spheroid extrusion at the periphery of the cisterna and is finally separated off as a membrane-bound granule (Plate 71). Clear vesicles appear to be budded off from the ends of the cisternae in a similar manner to the granules and may also be formed by the breaking up of an

PLATE 69. Electron micrograph of the cortical region of the ingluvial ganglion. The upper portion of this field is occupied by the neural lamella (nl) in whose acellular matrix can be found collagen fibrils (cf) and tracheoles (tr). Immediately beneath the neural lamella is the perineurium (p). Note the system of intercellular clefts (icc) and intercellular spaces (ics), which eventually open out at the base of the neural lamella (arrows). Also the perineurial nucleus (pn) and mitochondria (m). Membranes of the glial system (gl) indent the cytoplasm of the perikaryon (pk) to form characteristic trophospongia (t). Gliosome (gs).

entire cisterna into smaller fractions which then round off to form vesicles. Freshly elaborated neurosecretory granules measure 70-100 nm in diameter, but a whole range of granule sizes up to a maximum diameter of 500-600 nm are present in the vicinity of the Golgi apparatus. The perikarya, in common with those in the hypocerebral ganglion, contain only the electron-opaque variety of neurosecretory granule.

The neuropile

As in the hypocerebral ganglion a number of different Axon Types can be recognised in each sectioned field of the ingluvial ganglion neuropile (Plates 72-74):

Axon Types 1-5 - These profiles correspond exactly to Axon Types 1-5 in the hypocerebral ganglion neuropile.

Axon Type 6 - Axon profiles containing electron-opaque neurosecretory granules, 200-300 nm in diameter.

Axon Type 7 - Axon profiles containing a heterogeneous population of neurosecretory granules which range in density from electron-opaque to electron-lucent and measure 200-300 nm in diameter. These were only very occasionally encountered.

Mitochondria and small empty vesicles, 30-50 nm in diameter, can often be found in Axon Types 3-7 but neurotubules are less obvious (Plates 73 and 74). In Plate 74 an electron-opaque granule appears to be in the process of budding off a

PLATE 72. A survey field of the ingluvial ganglion neuropile. Note the presence of four different axon types: 1 - containing neurotubules (nt) and mitochondria (m) but devoid of neurosecretory material; 2 - containing synaptic vesicles; 3 - containing electron-opaque neurosecretory granules only; 4 - containing electron-opaque and electron-lucent neurosecretory granules. small electron-lucent vesicle in a manner similar to that described by SCHARRER (1968) in Periplaneta.

The ingluvial ganglion neuropile in Blabera and Schistocerca (CHANUSSOT et al., 1969) contains two kinds of granule which often coexist in the same axon profile: (1) Electron-opaque granules, ca. 150 nm in diameter, but whose density and diameter show considerable variation. Such granules match those found in Axon Types 3 and 4 of the present work; (2) Vesicles with a diameter of 65 nm, the majority of which are clear with but a few containing electron-opaque material. The empty vesicles may correspond to those small empty vesicles frequently found in neurosecretory axon profiles in the Locusta ingluvial ganglion neuropile, although the vesicles of CHANUSSOT et al. are slightly larger. Non-neurosecretory axons (Axon Type 1) are also apparent in CHANUSSOT et al.'s electron micrograph of the neuropile in Blabera.

Frontal Connective

The two frontal connectives are almost circular in cross-section and one or other almost invariably accommodates a trachea which runs the length of the nerve between the centrally located axons. The nerve sheath (neural lamella + perineurium) overlies the glial cells in the cytoplasm of

PLATE 75. A transverse section of the frontal connective. The axon population is composed of a few large axons (lax) and numerous medium (max) and small axons (sax). One or more mesaxon turns invests each large axon, the space between the glial membranes periodically dilating to form large extracellular spaces (ecs). Neurosecretory material (ns) is located exclusively with the medium- and small-sized axon profiles. Note also the neural lamella (nl), perineurium nucleus (pn), gliocyte nucleus (gn), tracheolar cell (trc), small tubular mitochondria (sm) and large mitochondria (lm).

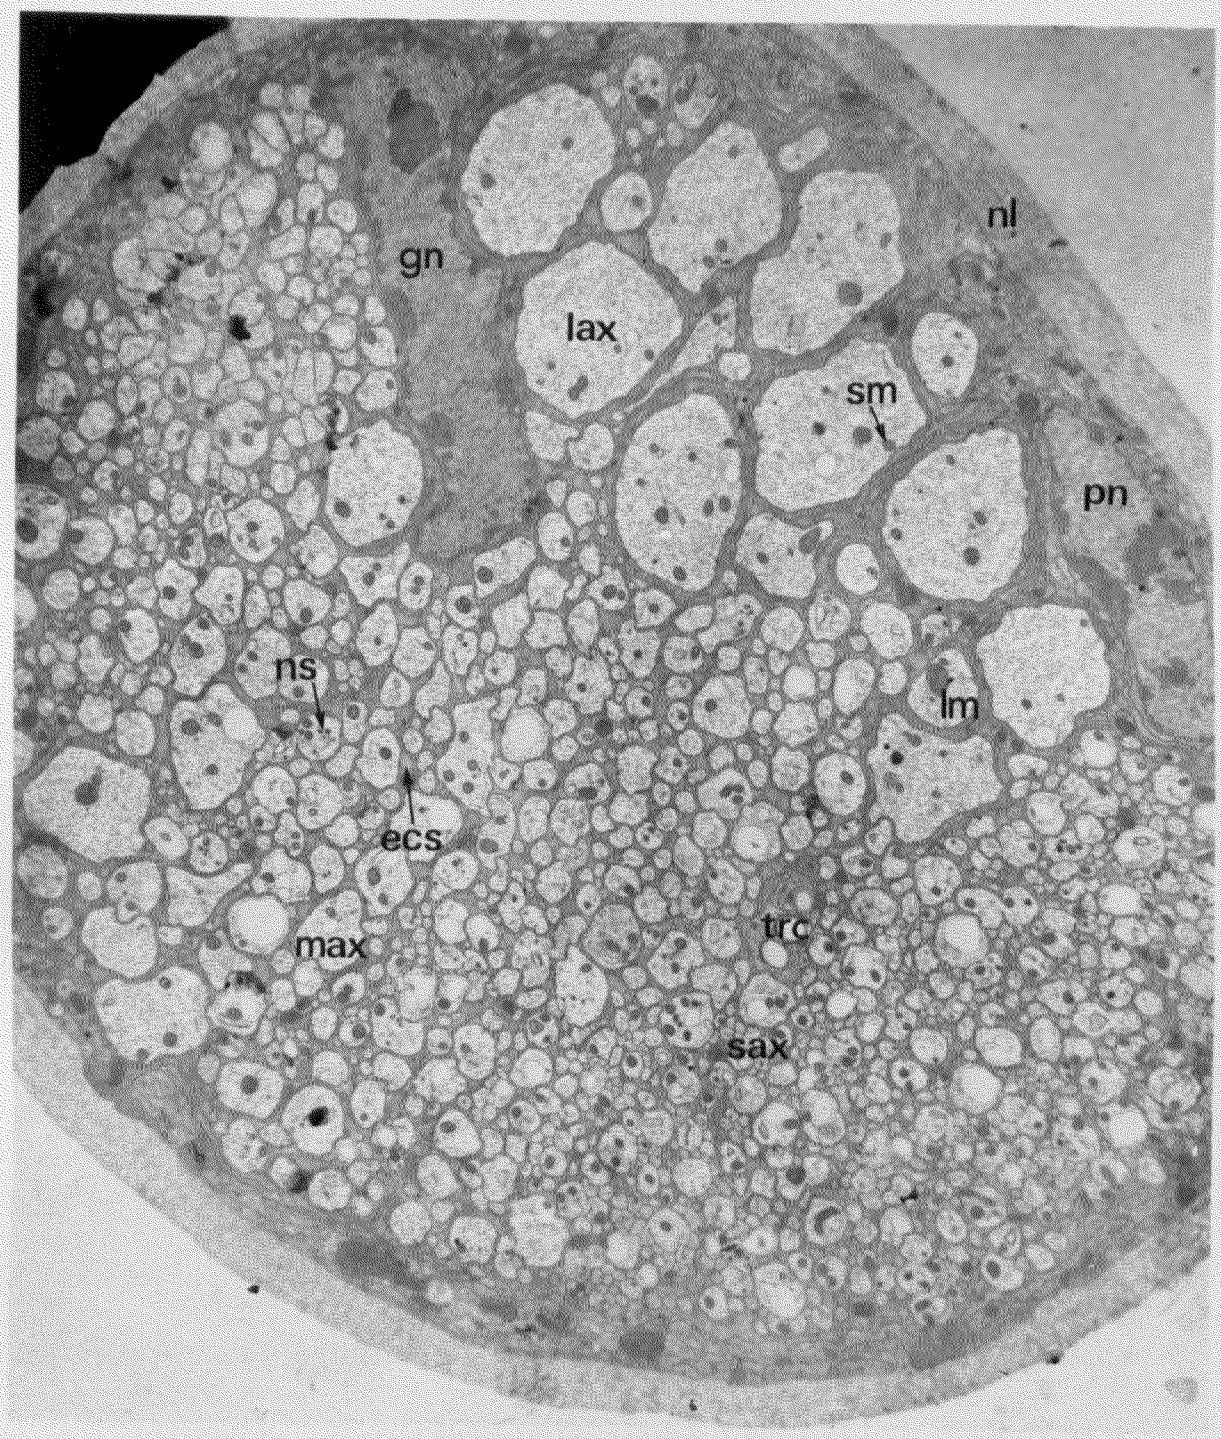
PLATE 75



which are embedded the axon cylinders (Plate 75).

The nerve sheath

The neural lamella, which lies outside the perineurium, has the typical structure, being composed of a multidirectional meshwork of collagen-like fibrils embedded in an amorphous matrix.

Numerous tubular mitochondria occur in the cytoplasm of the perineurial cells and the sinuous lateral cell walls occasionally diverge to form intercellular spaces. Near their bases the lateral walls are held together by septate desmosomes (Plate 76). Compared to the hypocerebral and ingluvial ganglia, the system of lateral cell walls and intercellular spaces in the frontal connective is far less extensive. The nuclei of the perineurial cells are flattened and contain dense clumps of chromatin material. A few scattered Golgi complexes, consisting of several stacked saccules in close company with empty vesicles, can be found in the perineurial cytoplasm. Other cell organelles include microtubules, rough membrane-bound cisternae of the endoplasmic reticulum and free ribosomes. Vacuoles, sometimes containing membrane remnants, can also be detected in the cytoplasm (Plate 77). These probably represent the former site of dense granules

PLATE 76. A section taken through the nerve sheath of the frontal connective showing the large numbers of mitochondria (m) located in the perineurium (p). The lateral cell walls, which are held together by septate desmosomes (sd), frequently dilate to form intercellular spaces (ics). Note also the neural lamella (nl), profiles of rough endoplasmic reticulum (rer), Golgi complexes (go), glial processes (gl), axon packed full of neurosecretion (ns), and opening of the intercellular cleft (icc) immediately beneath the neural lamella (arrow).

Magnification x 17,100.

PLATE 77. A field including a group of large axon profiles (lax) within the frontal connective. The axons are ensheathed by glial cell processes (gl) the plasma membranes of which diverge periodically to delimit extracellular lacunae that become filled with an amorphous material (*). Note also neural lamella (nl), perineurium (p), neurotubules (nt), vacuole (vc) probably representing the former site of a dense granule, and gliosomes (gs).

77

that have been extracted during glutaraldehyde fixation. The exact nature and function of these granules is obscure (LANE, 1968).

The neuroglia

The glial system is extensive, the cell bodies forming a layer beneath the perineurium and their narrow processes extending right to the centre of the frontal connective, between the axon profiles. The gliocyte nucleus is usually located peripherally but can sometimes be detected lying in the midst of the axon population. It is often indented to conform to the contours of nearby axon cylinders (Plate 75). Mitochondria, Golgi saccules and vesicles, rough membrane-bound cisternae of the endoplasmic reticulum, microtubules and gliosomes can be identified within the glial cytoplasm.

In the frontal connective the large axons are surrounded by one or more mesaxon turns. The space between the closely applied glial membranes, the extracellular cleft, periodically dilates to form large extracellular spaces which are filled with an electron-dense material, thus making them easily recognisable (Plates 75 and 77). According to ASHHURST (1961) and SMITH and TREHERNE (1963) this material is an acid mucopolysaccharide. Medium and small sized axons tend not to possess an individual glial membrane wrapping, but instead lie

free in the glial cytoplasm. They are, therefore, still isolated from one another except where they aggregate together to form 'axon clumps'. Such axon groupings share a common glial investment (Plate 79). The axolemma of the small axons is often in direct contact with the electron-dense material contained in the extracellular spaces (Plate 78).

The axon population

The transversely sectioned field of the fourth instar frontal connective presented in Plate 75 contains ca. 1200 axon profiles. Two classes of axon are recognised:

1. Large axons - these measure 1.7-2.6 μm in diameter and number 13. Their axoplasm contains many neurotubules as well as scattered mitochondria. The neurotubules, which are aligned in arrays roughly parallel to the limiting plasma membrane, resemble morphologically the microtubules in perineurial and glial cells. Both measure ca. 20 nm in diameter and appear, in transverse section, as minute empty vesicles. The precise function of the neurotubules is unknown although it is suggested that they may play some part in cytoplasmic flow or have a skeletal function (GRAY, 1970). Two distinct sizes of mitochondria occur in the large axons. In the smaller and more numerous type of mitochondrion the cristae

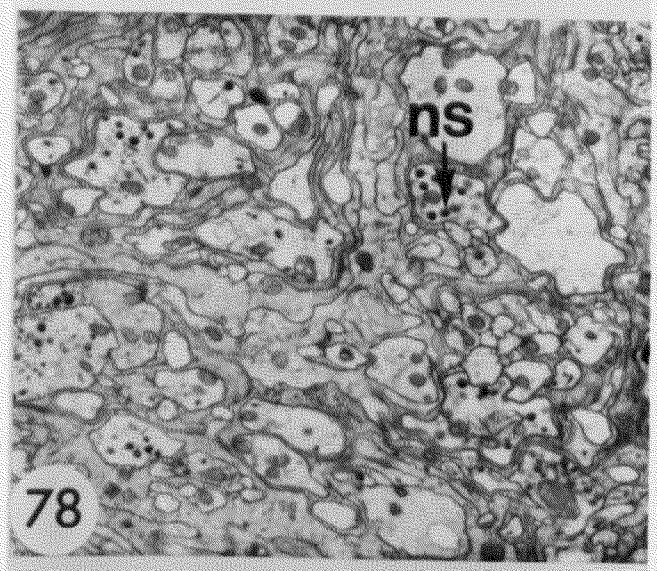
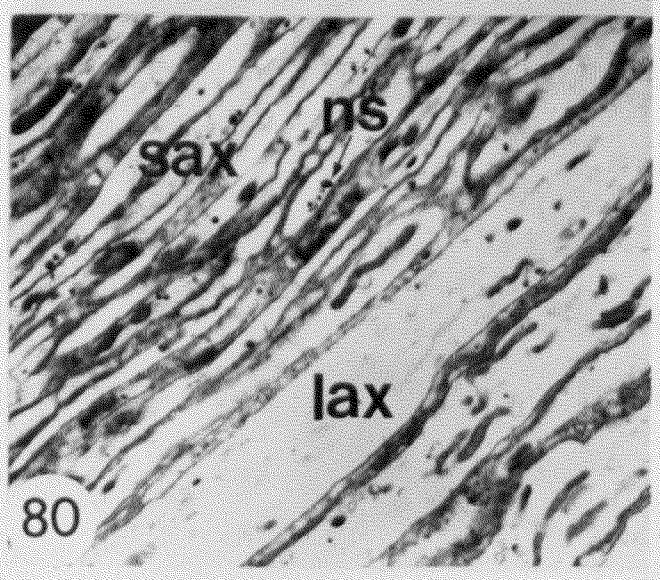
PLATES 78–80





appear either in the form of parallel lamellae or as concentric whorls. These types of arrangement are also adopted by cristae in the larger and rarer type of mitochondrion. A similar diversity in mitochondrial size and structure is also evident in the axons of the adult blowfly (OSBORNE, 1966).

2. Medium and small sized axons - these constitute the rest of the axon population and measure 0.06-1.3 μm in diameter. Neurotubules and small and large mitochondria can be found in medium and small sized axons together with a third type of axonal inclusion, the neurosecretory granule (Plates 75, 78, 79 and 80). By far the most predominant type of granule is the electron-opaque variety measuring 100-200 nm in diameter. A few grey granules of similar size range occasionally occur in the same axon as the electron opaque granules.

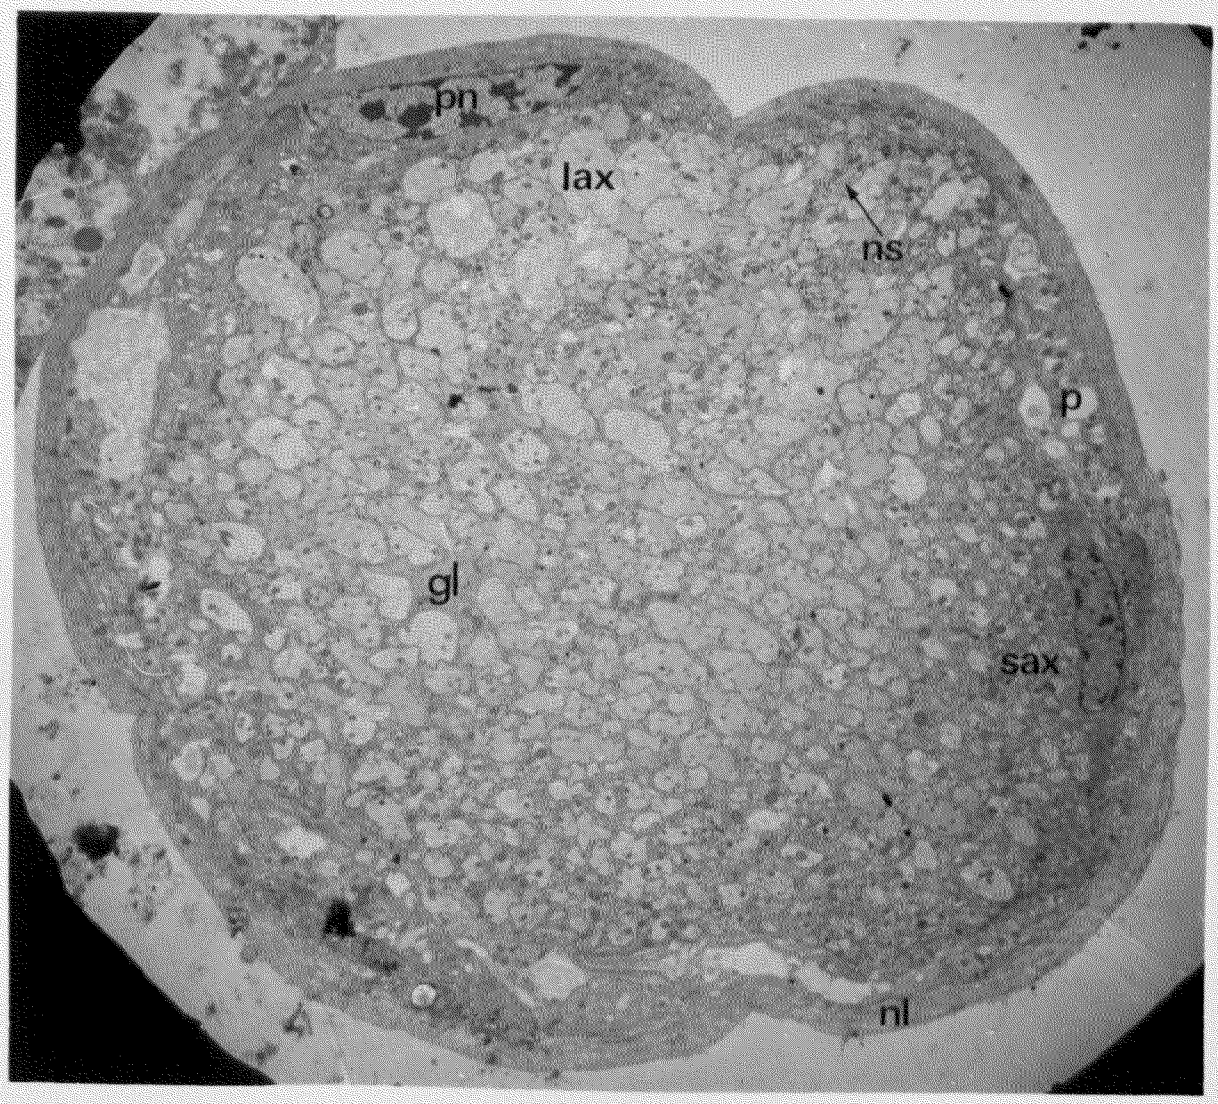
Recurrent Nerve

The recurrent nerve, which is a good deal thicker than the frontal connective, is approximately circular in cross-section. The centrally positioned axon population is invaded by the glial system and both are encapsulated by the nerve sheath (neural lamella + perineurium).

PLATE 81 A transverse section of the recurrent nerve. Note large axons (lax), small axons (sax), neurosecretion (ns), neural lamella (nl), perineurium (p), perineurium nucleus (pn) and glial process (gl).

Magnification x 4,100.

PLATE 81



The nerve sheath and neuroglia

In their ultrastructural organisation the neural lamella, perineurium and neuroglia do not differ significantly from these layers in the frontal connective. Some of their more important features are illustrated in Plates 81-84.

The axon population

At the level at which the section presented in Plate 81 is taken the fourth instar recurrent nerve contains approximately 2,200 axons in transverse profile, nearly twice the number counted in the frontal connective of the same instar (Plate 75).

Unlike the frontal connective, where a few large axons stand out from the rest of the axon population, there exists in the recurrent nerve a uniformly graded series of axon sizes, ranging from the smallest at 0.08 μm up to the largest at 2.7 μm in diameter. The disposition of the axons in the frontal connective and recurrent nerve is also different. Thus in the frontal connective the relatively few large axons tend to be grouped together near the edge of the axon population while in the recurrent nerve the larger axons may occupy a central position or display no organised grouping pattern whatsoever, as in Plate 81. The very small axons are

PLATE 82. A longitudinal section of the recurrent nerve. Note granules of neurosecretion in the small axons (sax), large axons (lax), perineurium (p) and gliocyte nucleus (gn).

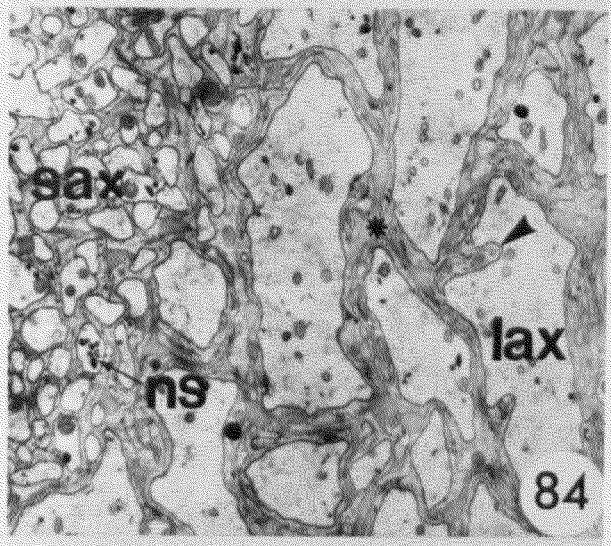
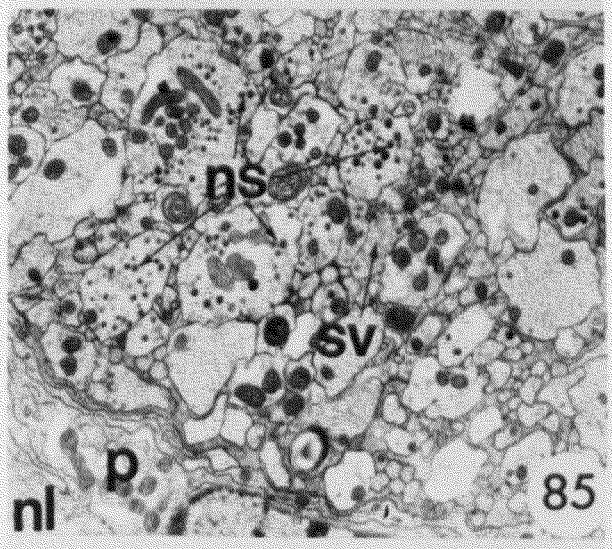
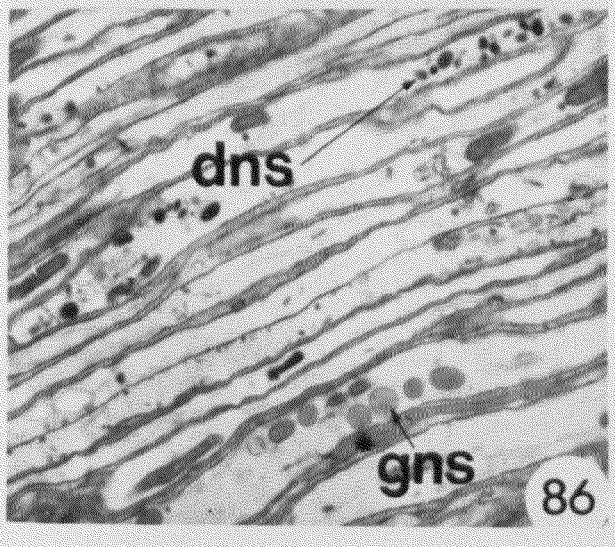
PLATES 84–86







invariably located close to the periphery of the axon population. The shape of the axons, particularly the large axons, in the recurrent nerve varies considerably, especially in transverse profile. In Plates 81, 83 and 85 the margins of the axons are frequently indented either by fellow axons or by glial cell cytoplasm, while in Plate 82 the axons are smooth in outline.

The larger axons, like those in the frontal connective, are non-neurosecretory. They contain neurotubules and small and large mitochondria whose cristae adopt a parallel lamellate or concentric whorl pattern of arrangement. Neurosecretory granules are found only in the medium and small sized axons which may also contain neurotubules and small and large mitochondria. The vast majority of granules are electron-opaque and measure 100-200 nm in diameter. Grey granules, 150-220 nm in diameter, are far less common (Plate 86). In Plate 85 several axon profiles contain a fourth type of axonal organelle, small clear vesicles 30-40 nm in diameter. These are almost certainly synaptic vesicles (SMITH, 1968).

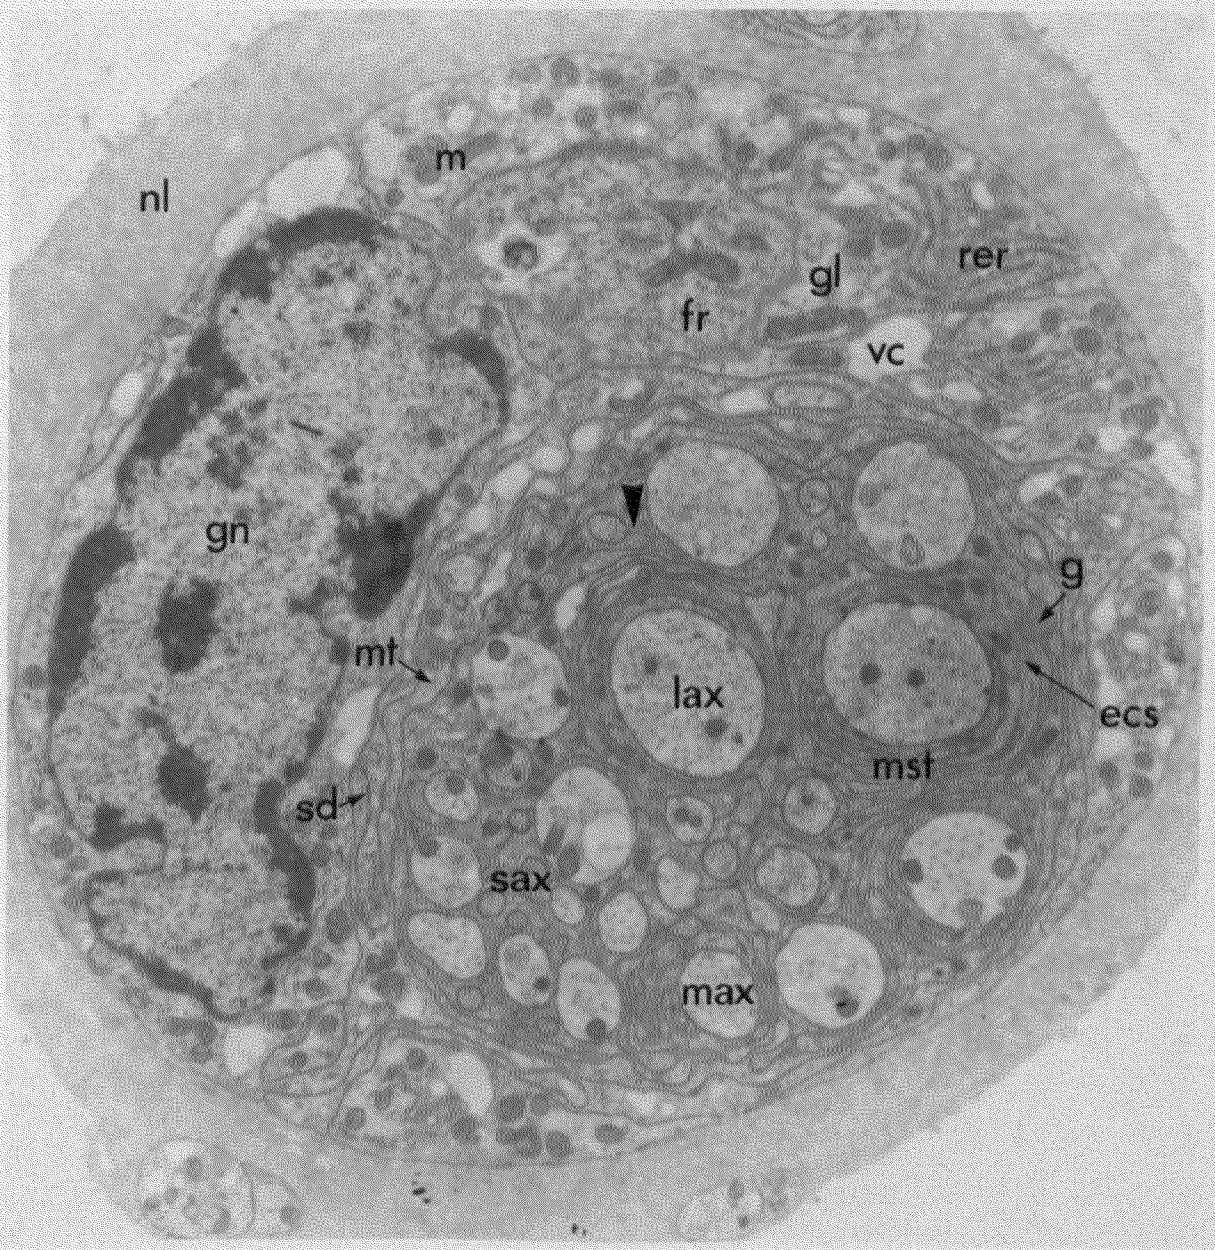
Posterior Pharyngeal Nerve

The posterior pharyngeal nerves in fourth instar nymphs were sectioned close to where they enter the frontal ganglion. In this position they are composed of an outer neural lamella

PLATE 87. A transverse section of the posterior pharyngeal nerve. Profiles of rough endoplasmic reticulum (rer), free ribosomes (fr), gliocyte nucleus (gn), microtubules (mt), gliosomes (g) and numerous mitochondria (m) can be detected within the glial cytoplasm (gl). Note that the cisterna of one rough endoplasmic reticulum profile is confluent with a large vacuole (vc). The axon population is composed of large (lax), medium (max) and small axons (sax). Each large axon is invested by one or more mesaxon turns (mst), the plasma membranes of the glial processes periodically diverging to form extracellular spaces (ecs). The amorphous material contained within these spaces may be in direct contact with the axolemma (arrow). Neural lamella (nl), septate desmosomes (sd).

Magnification x 12,900.

PLATE 87



inside of which lie the glial cells and axon cylinders (Plate 87).

The neural lamella and neuroglia

Tracheoles and isolated axons can be detected in the mottled background substance of the neural lamella as well as the usual collagen-like fibrils.

In the posterior pharyngeal nerve it is not possible to distinguish between perineurial cells and glial cells. This is also the case in small peripheral nerves in other insects (EDWARDS et al., 1958a,b, HESS, 1958; WIGGLESWORTH, 1959). The cells lying between the neural lamella and the axon population in the posterior pharyngeal nerve are considered to be glial cells. The glioplasm of these cells contains profiles of rough endoplasmic reticulum, a few scattered Golgi complexes, many microtubules, free ribosomes, gliosomes, mitochondria and a large gliocyte nucleus. Vacuoles of various shapes and sizes are also present and these, one must assume, were filled with material that has been removed during the cellular fixation process. One such vacuole is confluent with the cisterna of a rough endoplasmic reticulum profile (Plate 87). Contiguous glial cell membranes are often held together by septate desmosomes.

The larger axons in the posterior pharyngeal nerve enjoy at least one mesaxon fold while the rest are partially surrounded by glial membranes or lie free in the glioplasm. The closely-applied glial membranes frequently dilate to form larger extracellular spaces which contain an electron-dense substance similar to that found in the glial system surrounding the axons in the frontal connective and recurrent nerve (Plate 87).

The axon population

The transversely sectioned field of the fourth instar posterior pharyngeal nerve presented in Plate 87 contains 32 axon profiles which range in diameter from 0.2-1.7 μm. Their axoplasm contains neurotubules and many small and a few large mitochondria whose cristae adopt the now familiar parallel lamellate or concentric whorl pattern of arrangement.

A few sections also included fine branches of the posterior pharyngeal nerve (Plates 88 and 89). In these the perineurium is entirely absent and the scattered axons lie within the glial cytoplasm. Some of the axons contain electron-opaque neurosecretory droplets, measuring up to 220 nm in diameter, mingled with empty vesicles, 60-200 nm in diameter.

It is now clear that the nerve described by ANSTEE (1968) as being the recurrent nerve (Plates 5 and 6) is in fact the posterior pharyngeal nerve which of course runs very close and parallel to the recurrent nerve before entering the frontal ganglion.

PLATE 88. Electron micrograph of a section through a branch of the posterior pharyngeal nerve. Neurosecretion (ns) is present in two axons (ax) located immediately below the neural lamella (nl). Glial system (gl), gliocyte nucleus (gn).

Magnification x 10,700.

PLATE 89. Longitudinal section of a branch of the posterior pharyngeal nerve. Once again neurosecretory material (ns) can be detected in an axon (ax) lying immediately below the neural lamella (nl). The axon contains empty vesicles (ev) and part-empty vesicles (arrows). Note also the neural lamella (nl), glial system (gl), rough endoplasmic reticulum (rer), mitochondria (m) and septate desmosomes (sd).

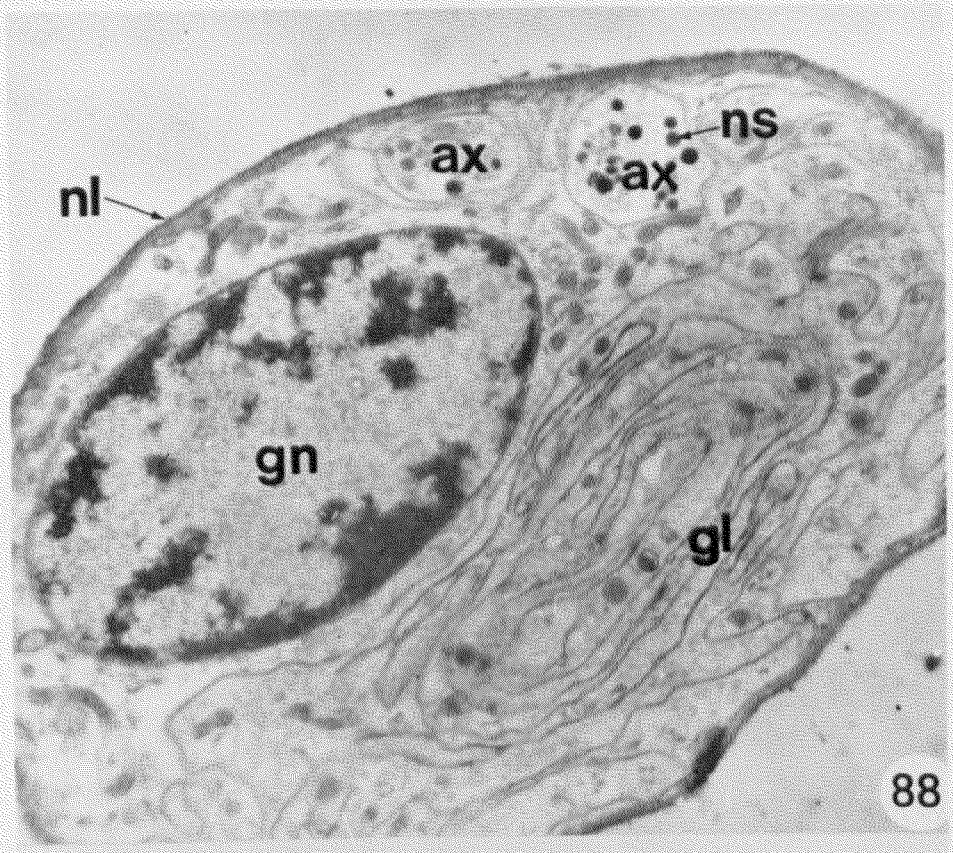
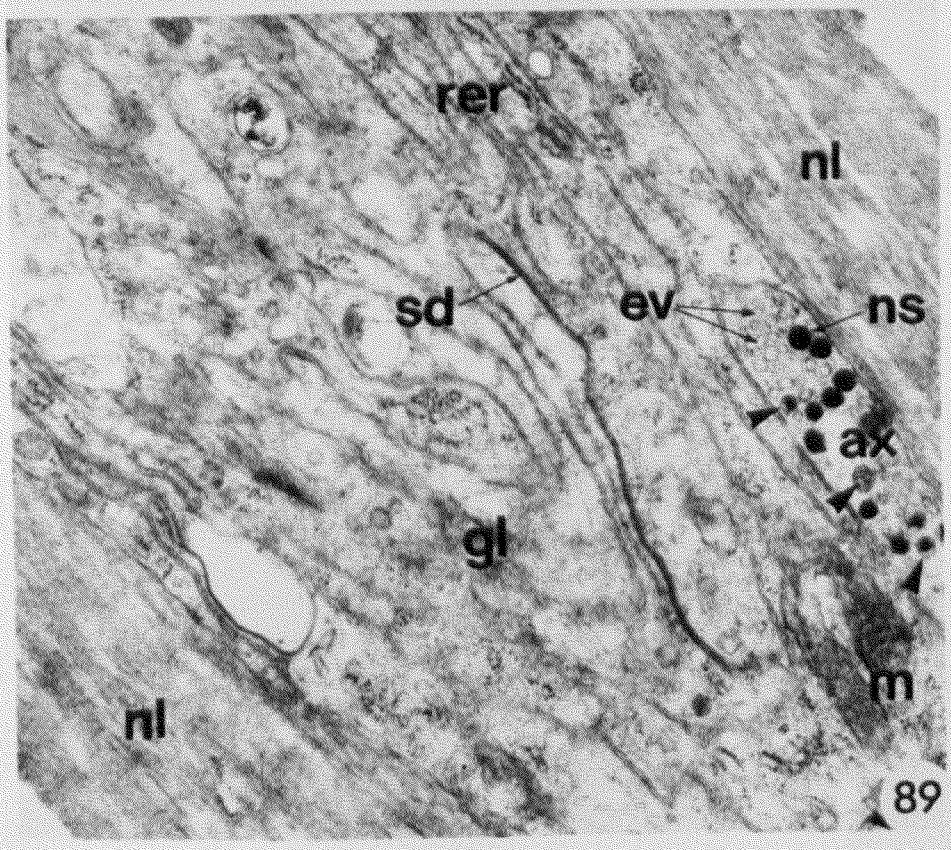
PLATES 88 – 89



88



89

SMITH and TREHERNE (1963) and ASHHURST (1968) review the functions of the neural lamella in insects. Its most obvious role is a mechanical one, that of maintaining the form of the ganglion or nerve, and in this it is helped by the collagen-like fibrils contained within the mucopolysaccharide matrix. At the same time the neural lamella remains permeable to ions and molecules that are exchanged between the haemolymph and the underlying perineurial cells.

MADDRELL and TREHERNE (1967) suggest that the perineurial cells influence axonal conduction by preserving within the ganglion or nerve an extracellular ionic balance that is very different from that in the haemolymph. According to these authors the long sinuous intercellular channels are employed in an osmoregulatory capacity, maintaining within their confined spaces solutions of high concentrations whose function it is to provide an osmotic 'buffer' between the haemolymph and the tissues underlying the cells of the perineurium. WIGGLESWORTH (1960) has shown histochemically that the perineurial cells take up nutrient precursors diffusing through the neural lamella from the haemolymph and pass them on to the underlying glial cells. Ion transport and food mobilization are processes requiring much metabolic energy and this accounts for the presence of the large numbers of mitochondria characteristically resident in perineurial cells. The perineurial cells are also held to be responsible for the secretion of the neural lamella (SCHARRER, 1939; ASHHURST, 1965; LANE, 1968).

The trophic function of the neuroglia, in supplying glycogen and lipids to the neurones, has been demonstrated

by WIGGLESWORTH (1960) and TREHERNE (1960). In favourable sections glycogen granules could be detected in the glial fingers which indent the peripheral cytoplasm of the perikarya in the hypocerebral and ingluvial ganglia. Glycogen granules also occur in the glial cell bodies, in the narrow glial processes entering the neuropile, and in the glial lamellae separating the neurone cell bodies from the edge of the neuropile. Axo-somatic and axo-dendritic synapses, which are commonplace in the vertebrate nervous system do not occur in insects because of the unbroken glial investment around the perikarya (CAJAL and SANCHEZ, 1951; SMITH and TREHERNE, 1963). Synaptic contact within the neuropile is to a certain extent defined by the glial processes entering this region (SMITH and TREHERNE, 1963). The acid mucopolysaccharide present in the extracellular spaces of the glial system in peripheral nerves functions to restrict the movement of ions and molecules in these spaces and also forms a significant cation reservoir, thus maintaining a relatively high sodium environment at the axon surface (TREHERNE and MORETON, 1970).

The neurone cell bodies of the hypocerebral ganglion in 10-day-old adults contain less neurosecretion than the perikarya of either the ingluvial ganglion or the frontal ganglion (ANSTEE, 1968) in adults of a similar age. Interestingly enough NORMANN (1965) could find hardly any neurosecretory material in the perikarya of the blowfly hypocerebral ganglion.

The most conspicuous feature of the perikarya in the ingluvial ganglion, and to a lesser extent in the hypocerebral ganglion, is the presence within them of 'giant' granules of neurosecretion. Freshly elaborated neurosecretory granules measure 60-100 nm in diameter, but in close proximity to the Golgi apparatus can be found a whole range of granule sizes up to a maximum diameter of ca. 500 nm. Giant neurosecretory granules also occur in the neurone cell bodies of the frontal ganglion where they measure 350-500 nm in diameter (ANSTEE, 1968). The giant granules are presumably formed by aggregation of smaller granules and according to GIRARDIE and GIRARDIE (1967) they represent a neurosecretory storage mechanism. The perikarya of the hypocerebral and ingluvial ganglia, like those of the frontal ganglion (ANSTEE, 1968) and most other insect ganglia, contain only one class of neurosecretory granule, namely the electron-opaque variety. The intrinsic secretory perikarya of the corpora cardiaca in Leucophaea (SCHARRER, 1963) and the alfalfa weevil, Hypera postica (TOMBES and SMITH, 1970), on the other hand, manufacture neurosecretory droplets of varying electron opacity. Whether or not such granules contain different hormones is at present unknown.

Neurosecretory granules differing in size and electron opacity occupy many of the axon profiles within the neuropile of the hypocerebral and ingluvial ganglia. Other axon profiles are non-neurosecretory in nature. As mentioned earlier Axon Types 1 - 5 are common to both the hypocerebral and ingluvial ganglia. The frontal ganglion neuropile (ANSTEE, 1968) contains axon profiles corresponding

to Axon Types 1 - 4 , while in the neuropile of the ingluvial ganglion of Blabera and Schistocerca (CHANUSSOT et al., 1969) can be found profiles which match Axon Types 1 , 3 and 5 . The single sectioned field of the Carausius hypocerebral ganglion neuropile presented by SMITH (1968) contains axon profiles which correspond to Axon Types 1 - 4 . Adopting the neurosecretory axon classification scheme of KNOWLES (1965, 1967), SCHARRER (1968) and CHANUSSOT et al. (1969), Axon Types 3 , 4 , 6 and 7 are peptidergic (A-type), carrying neurosecretory products of a proteinaceous nature, and Axon Type 5 is aminergic (B-type), transporting neurosecretory products of a monoamine character.

The presence of electron-lucent granules in Axon Types 4 and 7 can be interpreted in a number of different ways. They may, for example, contain neurosecretory material different to that in the electron-opaque granules and which is dissolved out by the fixative. Alternatively, they may contain a different sort of neurosecretion which happens to be electron-lucent (SMITH and SMITH, 1966; SCHARRER, 1968). A third explanation, and one for which there exists a certain amount of ultrastructural evidence, is that advanced by SCHARRER (1963) and BLOCH et al. (1966). These authors suggest that the treatment of the tissue in preparation for electron microscopy may cause the electron-opaque granules to swell and burst their membranes. Alternatively, rupture may occur because some granules are more fragile than others. Either way, a gradual emptying of the granule content occurs which eventually leads to a complete loss of electron density. In Plate 67 a Type 4 axon contains several electron-lucent granules whose membranes appear to have been ruptured.

Axon Type 2 , which may well be another region of Axon Type 1 , contains vesicles whose dimensions are the same as those of synaptic vesicles. The possible mode of formation of such vesicles is discussed by DE ROBERTIS (1964), VOLLRATH (1969) and HUDDART (1971b). Small vesicles (ca. 30 nm in diameter) are frequently encountered in Axon Types 3 - 5 and may be synaptic in nature too. Other vesicles occurring in Axon Type 5 measure 50-60 nm in diameter and occasionally contain dense material. Vesicles of a similar type have been detected in the ingluvial ganglion neuropile of Blabera and Schistocerca by CHANUSSOT et al. (1969) and are thought to contain a primary catecholamine.

The frontal connective and posterior pharyngeal nerve in fourth instar nymphs are both composed of a few large axons and many smaller axons. The large axons are invariably supplied with a private glial sheath which enables them to conduct at a faster rate than the more poorly insulated smaller axons (HUDDART, 1971a). Almost certainly the large axons are motor and the smaller ones sensory or motor (WIGGLESWORTH, 1969; HUGHES, 1965; BLANEY and CHAPMAN, 1969; HUDDART, 1971a). It is prudent, however, to heed the warning of PEARSON et al. (1970) who point out the dangers of using axon diameter as the sole criterion of function. Electrophysiological recordings from both large and small axons are obviously needed to supplement the ultrastructural observations presented here.

In the recurrent nerve and frontal connective neurosecretory material can be found only in the smaller axons. The neurosecretory axons in these nerves, and in the fine branches of the posterior pharyngeal nerve, contain mainly

the electron-opaque class of granule, grey granules being only rarely encountered. The large non-neurosecretory axons present in all three nerves presumably correspond to those found in the neuropilar region of the frontal and hypocerebral ganglia.

Giant neurosecretory granules of the sort found in the neuronal perikarya of the frontal, hypocerebral and ingluvial ganglia do not occur in the neuropiles of these ganglia or in the axons of the three peripheral nerves. One must assume, therefore, that they are broken down into granules of smaller size, probably by lysosomes (GIRARDIE et GIRARDIE, 1967), prior to transport out of the perikaryon.

CHAPTER IV

DISCUSSION

The morphology of the anterior stomatogastric nervous system in Locusta is more complex than previous studies have indicated (ALBRECHT, 1953; CLARKE and LANGLEY, 1963b, c). For example, the posterior pharyngeal nerve branches profusely and links the frontal ganglion to many structures including the musculature of the pharynx and oesophagus, the recurrent nerve, the hypocerebral ganglion, the tritocerebrum, the corpus cardiacum, the nervus corporis cardiacum III (NCC III) and the nervus corporis allatum II. Information from sensory cells on the pharynx can, therefore, reach the tritocerebrum and corpora cardiaca independently of the frontal connectives, frontal ganglion, recurrent nerve and hypocerebral ganglion. The complex nerve pattern, offering as it does many alternative routes between the foregut and the neuroendocrine system, increases the insect's chances of being able to adjust to the effects of any particular operation and of continuing the growth and moulting cycle. The ability of locusts to adjust to various surgical procedures is well illustrated by the work of HASKELL and MORDUE (1969). These authors demonstrated a recovery in feeding in hoppers after palpal removal and showed that other receptors were able to assume the role formerly discharged by the palps.

They deduced a rearrangement of the nervous integration mechanism to allow information from these other receptors (antennae and A_3 receptors of the clypeo-labrum) to be utilized instead.

The neuropilar region of the hypocerebral and ingluvial ganglia contains many A-type and relatively few B-type (KNOWLES, 1965; SCHARRER and WEITZMAN, 1970) neurosecretory fibres, as well as a certain number of non-neurosecretory fibres. It therefore resembles the ingluvial ganglion neuropile in Schistocerca gregaria and Blabera craniifer (CHANUSSOT et al., 1969; CHANUSSOT, 1972). The large intrinsic perikarya of the hypocerebral and ingluvial ganglia, like those of the frontal ganglion (ANSTEE, 1968; CAZAL et al., 1971), manufacture only the electron-opaque class of neurosecretory granule. Such granules are widely distributed and occur not only in the perikarya but also in the neuropilar region of each ganglion, in the smaller sized axons of the frontal connectives and recurrent nerve, and in axons contained in fine branches of the posterior pharyngeal nerve. At the light microscope level STRONG (1966) has detected neurosecretory material in the inner and outer oesophageal nerves in Locusta and future ultrastructural investigation will almost certainly reveal neurosecretion to be present in other nerves of the locust stomatogastric nervous system. But what is the functional significance of this neurosecretion?

There is increasing evidence to support the view that biogenic amines are involved in the control of foregut

muscular activity (FREEMAN, 1966; COOK et al., 1969). In this context it is interesting to note that CHANUSSOT et al. (1969) have localised a biogenic amine (probably dopamine or noradrenaline) in the ingluvial ganglion neuropile and in one of the ganglionic nerves in both Schistocerca and Blabera. Further, these authors believe that the primary catecholamine, whatever its true identity may be, is associated with the B-type neurosecretory fibres, that is those axons containing granules and vesicles ca. 65 nm in diameter. A similar kind of relationship between biogenic amines and B-type neurosecretory fibres has been deduced in the beta lobes of Periplaneta americana (MANCINI and FRONTALI, 1970) and in various vertebrate nervous tissues (HOKFELT, 1968; TAXI, 1968). The corpora cardiaca in Leucophaea maderae contain a few B-fibres, and SCHARRER (1963, 1968) suggests that these fibres may regulate the release of neurohormone from adjacent peptidergic A-fibres.

The abundance of neurosecretion in the ingluvial ganglion neuropile has led CHANUSSOT and his colleagues to suppose that this ganglion functions as a neurohaemal organ, storing neurosecretory material in the neuropilar axons and releasing it into the interaxonal glial cell extensions. The hypocerebral and ingluvial ganglia neuropiles in Locusta are likewise charged with copious amounts of neurosecretion, but whereas in the ingluvial ganglion much of this material is elaborated in the intrinsic perikarya, in the hypocerebral ganglion the neurone cell bodies appear to contribute very little neurosecretion to the neuropilar store. As a general rule the glial cell elements were found to be poorly represented in

the hypocerebral and ingluvial ganglia neuropiles and "axone-cellule gliale" contacts of the sort described by CHANUSSOT et al. (1969) and CHANUSSOT (1972) were not readily apparent in the sections of Locusta material examined.

Neurohaemal release sites, such as occur on the medial nerve in Schistocerca (BRADY and MADDRELL, 1967) and on the nervi corporis allati II in Acheta domesticus (WEBER and GAUDE, 1971), were not encountered in any section of the frontal connective or recurrent nerve. Some of the fine branches of the posterior pharyngeal nerve did, however, contain neurosecretory axons which were located immediately below the neural lamella. Release of neurosecretion into the haemolymph might be taking place since characteristic empty vesicles (SCHARRER, 1968) were present in the axon together with undischarged neurosecretory granules. The source of this neurosecretory material remains open to question but it could not have been derived from the main posterior pharyngeal nerve trunk since this was found to be devoid of neurosecretion. The material may have come from the NCC III. According to RAABE (1963a, 1964) this nerve is made up of axons of the tritocerebral neurosecretory cells and it has been shown during the course of the present study that the posterior pharyngeal nerve is linked to the NCC III.

Nerves containing neurosecretion run to a variety of tissues in insects (for references see OSBORNE et al., 1971) and it has been demonstrated by GOSBEE et al. (1968), WILKINS and MOTE (1970), and COOK and MILLIGAN (1972) that insect neurosecretory cells can conduct action potentials. By implicating the sensory cell bodies located on the surface

of the foregut one can speculate on the existence of reflex arcs in the stomatogastric nervous system. A nerve such as the inner oesophageal nerve, which is known to contain neurosecretion (STRONG, 1966), may have separate "neurosecretory" and "ordinary" motor nerve endings like, for example, the motor nerve of the ventral intersegmental muscles in Schistocerca (OSBORNE et al., 1971). The release of neurohormone and neurohumor at the nerve-muscle junction will be stimulated by the passage of spikes along the axons and the spike frequency will be determined, at least in part, by sensory imput reaching the neuronal perikarya from the surface of the foregut. BERN (1966) and SCHARRER (1969) believe that the function of neurosecretory innervation of tissues is to provide a more sustained stimulation than the classical neurohumoral type of activation which elicits responses of very short duration. The neurosecretory products may also have a trophic function, i.e. be involved in the growth and maintenance of the muscle tissue (OSBORNE et al., 1971).

ANSTEE (1968) has suggested that nervous impulses from the foregut sensory neurones may stimulate the release of neurosecretory material from the frontal ganglion perikarya. This material, travelling along the frontal connectives, then causes the release of neurosecretion from the medial neurosecretory cells and corpora cardiaca into the blood. The frontal connective neurosecretion may also stimulate the release of neurosecretion from the lateral neurosecretory cells of the pars intercerebralis. However, the rapid release of neurosecretory material from the neuroendocrine system, induced by feeding previously starved animals

(HIGHNAM et al., 1966; DOGRA and GILLOTT, 1971; HIGHNAM and WEST, 1971), can only be explained in terms of direct nervous stimulation. Therefore, the frontal connective neurosecretion, if it does play a stimulatory role, will be of importance over the long-term rather than the short-term period. The identification of synaptoid configurations (KNOWLES, 1967; SCHARRER, 1968), between frontal connective elements on the one hand and median or lateral neurosecretory elements on the other, would strengthen the above supposition that frontal connective neurosecretion does act as a neurochemical mediator. Some of the neurosecretory material carried in the frontal connectives may, in fact, find its way into the protocerebral neuropilar reservoir of HIGHNAM and WEST (1971). The assumption that neurosecretion in the frontal connective travels in the frontal ganglion $\longrightarrow$ tritocerebrum direction is supported by the results of preliminary ligature experiments, where a build up of neurosecretory material on the frontal ganglion side of the ligature has been demonstrated.

The remainder of Chapter V is devoted to a discussion on the effects of various surgical interruptions with the anterior stomatogastric nervous system on the processes of growth, new cuticle development and moulting.

The severance of the recurrent nerve either induces a hyperphagic-type response or has no adverse effect upon the insect apart from slightly lowering its growth rate. This

latter response is the only one reported by CLARKE and LANGLEY (1963b) for the operation in third instar animals, while the former response has previously been described in Phormia regina (see review by GELPERIN, 1971) and adult male Schistocerca (FRASER ROWELL, 1963). The induction of hyperphagia in Phormia depends on precisely where along its length the recurrent nerve is cut relative to a pair of stretch receptors contained in a link nerve running to the foregut surface (GELPERIN, 1967, 1971). Whether or not Locusta nymphs become hyperphagic may also be associated with the site of severance, and the posterior pharyngeal nerves appear to be in some way implicated in the determination of this response. Thus, fifth instar nymphs with both posterior pharyngeal nerves cut consume more food during the course of a single meal than control animals (BERNAYS and CHAPMAN, personal communication). These authors have also recently shown that the cutting of the recurrent nerve on its own has no effect upon the normal increase in resistance across the tips of the maxillary palps after the foregut has become filled with food, but that the cutting of the recurrent nerve plus the posterior pharyngeal nerves prevents this normal increase (BERNAYS and CHAPMAN, in press). A corollary of the latter observation is that the operated animals continue to respond to the presence of food and so become hyperphagic. In Phormia, Schistocerca and Locusta, then, hyperphagia is a response to surgical interference with a negative feedback pathway involved in inhibiting further feeding after filling of the foregut has been accomplished.

The cutting of the recurrent nerve, or its posterior extension beyond the hypocerebral ganglion, the oesophageal nerve (WILLEY, 1961), inhibits crop emptying over the short-term period (i.e. during the first 24 hr post-operative) in Periplaneta (DAVEY and TREHERNE, 1963) and Leucophaea (ENGELMANN, 1968), and over the long-term period in Leucophaea (SCHARRER, 1945; TAYLOR, 1969) and Melanoplus differentialis (DOGRA and EWEN, 1971). The short-term effects of the operation on crop emptying in Locusta were not investigated, but over the long-term period this process is not adversely affected. In those animals exhibiting a hyperphagic-type response almost the entire length of the gut become distended with food; this also happens in hyperphagic Phormia (EVANS and BARTON-BROWNE, 1960; GREEN, 1964; DETHIER, 1969).

In addition to its effects upon food consumption and food passage, severance of the recurrent nerve also induces the formation of tumour-like lesions in the foregut of many insect species (for literature review see TAYLOR, 1969), including Locusta (MATZ, 1961, 1963). TAYLOR considers that the invasive tumours in Leucophaea are an injury response to the overfull foregut but does not completely rule out the possibility of their being formed as a result of loss of neural innervation. HARKER (1963) suggests that the lesions are induced by humoral changes. Frontal ganglionectomy, an operation entailing severance of the recurrent nerve, also leads to the formation of tumours in the foregut of Locusta (ANSTEE, 1968; ROOME, 1968). Here the histological evidence suggests that, as in Leucophaea, they are caused by an overfull gut.

In accordance with CLARKE and LANGLEY (1963c) the cutting of one frontal connective has no effect upon the growth cycle in nymphal Locusta. On the other hand, the cutting of both frontal connectives (proximal to branches) does not, as these authors supposed, cause every operated animal to maintain a constant weight. The operation is a fairly straightforward one, yet when performed on animals of approximately the same age it yields a wide range of growth responses. Thus at one end of the growth spectrum lie those animals maintaining a constant weight and at the other those that more than double their operation weights. How, then, can this diverse effect upon growth be explained?

The site of connective severance was the same in every insect and care was taken not to damage other nerves during the operation. Surgical technique can, therefore, be ruled out as a cause of the variable growth response. There is evidence to indicate that the operation interferes with the process of crop emptying in acridids, and this in turn would influence growth. Thus ROOME (1968) reports that the cutting of both frontal connectives in third instar Locusta nymphs results in the majority of operated animals maintaining a constant weight, with but a few showing significant weight increases; the 'non-growers' invariably exhibiting distended crops at autopsy. The operation also adversely affects food passage out of the crop in adult Melanoplus (DOGRA and EWEN, 1971). By comparison, crop emptying in cockroaches is unaffected by the severance of both frontal connectives, at least over the short-term period (DAVEY and TREHERNE, 1963; ENGELMANN, 1968). The timing of the operation with regard to

prior feeding activity may, as ENGELMANN found following recurrent nerve severance in Leucophaea, be an important factor in determining the rate at which the crop empties. This implies that an insect with a full foregut at the time of the operation adjusts less well than one with an empty foregut. Such an idea is easy enough to test experimentally.

According to CLARKE and LANGLEY (1963c) and ANSTEE (1968) the frontal connectives play a role in stimulating the release of neurosecretion from the neuroendocrine system. The continued growth of some animals after the cutting of both frontal connectives distal to their branches provides clear evidence of the involvement of other nervous pathways in the control of neurosecretory release.

Severance of the anterior, median and posterior pharyngeal nerves has the opposite effect upon the growth cycle to that reported by CLARKE and LANGLEY (1963c) for third instars. Operated fifth instar nymphs exhibit twofold or more increases in weight and display an overall growth rate that is only slightly lower than that of the controls. There are two possible explanations for the discrepancy. The first of these assumes that the stomatogastric nervous system in third instar locusts is less extensive than in fifth instars, implying that the former group are neuromorphologically less well equipped to adjust to the effects of the operation than the latter group. The second possibility is that CLARKE and LANGLEY inflicted more damage upon the anterior stomatogastric nervous system than mere pharyngeal nerve severance. The operation obviously needs to be repeated on a large sample of newly moulted third instar nymphs and its effect

upon growth tested against that reported here for fifth instar nymphs.

Thus far, then, none of the operations involving severance of the nerves associated with the frontal ganglion have been shown to completely inhibit the growth cycle in each and every operated animal. Neither does the operation involving severance of both frontal connectives plus the recurrent nerve completely block growth in every operated adult locust. It is clear that after any of the above operations suitable alternative nervous pathways are open to the insect by which sensory information from the foregut can reach the neuroendocrine system. Over the long-term period the frontal connectives may play a more important role in the control of crop emptying than the recurrent nerve; the neural control of this process is certainly worthy of further investigation. It remains to be discovered whether in those operated animals exhibiting true growth the lower maximum weights attained compared to the controls are due to a drop in food consumption or to less efficient utilization of ingested food, or both.

CLARKE and LANGLEY (1963b, c) found that frontal ganglionectomy in third instar Locusta nymphs led to an immediate cessation of growth in every operated animal. They concluded that the operation acts by blocking the synthesis and/or release of neurosecretory material from the neuroendocrine system (CLARKE and LANGLEY, 1963d) but is without effect upon the feeding behaviour ("the intake of food, the amount in the gut, and defaecation proceed normally", CLARKE and LANGLEY, 1963b). The effects of frontal ganglionectomy on protein metabolism and RNA synthesis in Locusta nymphs,

as reported by CLARKE and GILLOTT (1965, 1967a, b), are held to be the result of a lack of neurosecretory material in the haemolymph rather than a lack of food material in the midgut ("the operated locusts were observed to eat frequently and to defaecate often; no obvious differences between these and normal locusts were observed in this matter", CLARKE and GILLOTT, 1965). In the present study, however, normal feeding behaviour could not be correlated with the maintenance of a constant body weight in any frontal ganglionectomised fourth or fifth instar locust. Food accumulated in the foregut of those operated animals maintaining a constant weight and passed through the gut unhindered in those exhibiting true growth (twofold or more weight increase). The vast majority of the frontal ganglionectomised locusts of ROOME (1968) maintained a constant weight after the operation and displayed a distended foregut at autopsy. Frontal ganglionectomy has an adverse effect on food movement in other acridids (ROUSSEL, 1966; HIGHNAM et al., 1966; HILL et al., 1966; GILLOTT et al., 1970; DOGRA and EWEN, 1971), but in the coleopteran Necrophorus vespillo normal alimentation and body weight increase occur after the operation (ROUSSEL, 1966).

Foregut muscular activity in Locusta is unaffected by the removal of the frontal ganglion (ROOME, 1968), while in Schistocerca its normal pattern of contraction and relaxation is changed following the removal of the hypocerebral ganglion (CLARKE and GRENVILLE, 1960). In both species movements of the foregut cease altogether in the absence of the ingluvial ganglia. Of the three stomatogastric ganglia, then, the frontal ganglion seems to play the least important role in

the control of foregut muscular activity. In its absence the pharynx and oesophagus presumably come under the influence of the hypocerebral ganglion and the fine nerve network that links it to these regions of the foregut. The oesophagus anyway displays a certain amount of myogenic activity, as does also the anterior region of the crop (ROOME, 1968). Thus, rather than influencing the normal peristaltic activity of the foregut musculature as HIGHNAM et al. (1966) suggest, the operation of frontal ganglionectomy appears to be exerting its effect at the level of the crop/midgut junction.

The neural control of crop emptying is complex and is fully understood in a limited number of insects only (see reviews by DAVEY, 1964; GELPERIN, 1971). In Leucophaea ENGELMANN (1968) concludes that "the opening of the proventricular valve appears to be controlled by either the ingluvial or the proventricular ganglion but that superimposed on these may be a certain amount of control by the frontal ganglion". It is clear that in Locusta frontal ganglionectomy has a variable effect upon crop emptying, and in this respect it resembles the operation of both frontal connective severance.

Frontal ganglionectomy can also affect food intake and food utilization. ROOME (1968) provides quantitative measurements to show that food consumption in operated Locusta nymphs is reduced in comparison to the controls. This, however, is presumed not to be the case in operated adult Melanoplus who, though they display greatly distended foreguts at autopsy and produce much less faeces than the controls, feed at an apparently normal rate (GILLOTT et al., 1970). The foreguts of a fair proportion of the frontal ganglionectomised animals

in the present investigation contained only moderate amounts of food at autopsy. In a few such animals the daily level of faeces production was the same as that in the controls but the body weight increases were much lower. Here the operation has interfered with the mechanisms of food utilization, presumably at the level of neurosecretory release (LANGLEY, 1962; GILLOTT, 1965).

In the normally growing locust neurosecretory material released from the corpora cardiaca regulates both the protein content of the haemolymph and the protein synthetic activity of the fat body (HILL, 1962, 1965; OSBORNE et al., 1968). In third instar (CLARKE and LANGLEY, 1963d) and fourth and fifth instar (ANSTEE, 1968; CLARKE and ANSTEE, 1971b) Locusta nymphs neurosecretory material accumulates in the nervi corporis cardiaci interni (NCC I) following removal of the frontal ganglion. CLARKE and LANGLEY consider that the operation has no effect upon food passage. The operated animals of ANSTEE maintained a constant weight and although this author makes no direct comment on the subject of food passage, the development of invasive tumours in the foregut of some of his operated animals, concluded by him on histological grounds to be caused by an overfull foregut, strongly suggests that crop emptying in these particular animals was inhibited by the operation. The few frontal ganglionectomised animals of ROOME (1968) that exhibited appreciable weight increases contained NCC I which, like those of the control animals, were devoid of stainable material. Unfortunately, this author did not investigate the NCC I in those operated animals maintaining a constant weight and displaying distended foreguts at autopsy.

In frontal ganglionectomised adult female Schistocerca (HIGHNAM et al., 1966) neurosecretory material piles up in the NCC I within two days of the operation, its accumulation coinciding with that of undigested food in the foregut. HIGHNAM and his collaborators consider that the operation increases the rate of synthesis and transport of neurosecretory material but has no adverse affects upon its release.

Frontal ganglionectomy in adult female Melanoplus (GILLOTT et al., 1970) has the same effect on crop emptying and hence body weight increase as in adult female Schistocerca, but an opposite effect upon the type A neurosecretory cells whose synthetic abilities are reduced after the operation. As GILLOTT et al. point out, the operation may lead directly to reduced activity in the cerebral neurosecretory cells (CLARKE and LANGLEY, 1963b, c, d) or it may affect these cells indirectly, via semi-starvation (HIGHNAM et al., 1966; HILL et al., 1966).

Brief mention should be made here of the effects of frontal ganglionectomy on the activity of the corpora allata in the above three acridids. These glands in Locusta nymphs (CLARKE and ANSTEE, 1971b) and adults (STROND, 1966) maintaining a constant weight after the operation show a marked reduction in size and, according to CLARKE and ANSTEE, appear histologically inactive. On the other hand the few Locusta nymphs of ROOME (1968) that increase in weight after frontal ganglionectomy contain corpora allata which are of similar dimensions to those of control animals. The corpora allata in operated adult female Schistocerca (HIGHNAM et al., 1966) are smaller than in the controls. However, it has been shown

(see review by MORDUE et al., 1970) that the volume of the corpus allatum is not necessarily a true indication of its synthetic ability and ideally other parameters should be measured. In this context GILLOTT et al. (1970) found that both the volume and the synthetic ability (measured autoradiographically) of the corpora allata in adult female Melanoplus are unaffected by the removal of the frontal ganglion. DOGRA and EWEN (1971) have implicated the corpora allata of Melanoplus in the control of general protein synthesis, while in adult female Locusta MINKS (1967) considers that these glands induce the formation of specific vitellogenic proteins in the fat body.

From the available evidence it appears that the effects on growth of various surgical interferences with the anterior stomatogastric nervous system are mediated primarily at the level of the crop/midgut junction. The operation may also reduce the endocrine potential of the insect in such a way that although normal or near-normal amounts of food are passed through the gut they are not fully utilized and converted into body tissue. There is plenty of scope for future work here. An obvious priority is a histological and autoradiographical examination of the neuroendocrine systems in growing and non-growing operated animals coupled with quantitative measurements of food intake and faecal production.

The development of a new cuticle is unaffected by the operations of one frontal connective severance or anterior, median and posterior pharyngeal nerve severance. On the other

hand, the cutting of both frontal connectives or the removal of the frontal ganglion have a variable effect upon the moulting cycle, some animals developing a new cuticle, others not (see also CLARKE and LANGLEY, 1963c; ROOME, 1968; PENZLIN, 1971).

The release of neurosecretion from the corpora cardiaca is a vital step in the moulting cycle, the neurosecretory material stimulating the prothoracic glands to secrete a hormone that activates the epidermal cells which in turn secrete a new cuticle (see reviews by WIGGLESWORTH, 1964, 1970). In Locusta, as in Rhodnius (WIGGLESWORTH, 1934, 1964), the prothoracic glands need to be exposed to the brain hormone for a certain 'critical' period in order that the moulting cycle might proceed to completion (JOLY et al., 1956; STRICH-HALBWACHS, 1959; GIRARDIE, 1964). CLARKE and LANGLEY (1963d), CLARKE and GILLOTT (1967a) and CLARKE and ANSTEE (1971b) provide histological and physiological evidence that frontal ganglionectomy interferes with the release of neurosecretion from the corpora cardiaca in Locusta nymphs. The operation has no effect on new cuticle development when performed after the critical period (CLARKE and LANGLEY, 1963c). If, however, the operation is carried out during the critical period two factors will determine whether or not the moulting cycle proceeds to completion. First, the extent to which the prothoracic glands have been activated by neurosecretion at the time of the operation (CLARKE and LANGLEY, 1963a, d). Second, the rate at which neurosecretory material is released into the haemolymph after the operation. Individual variation is also likely to exist in the degree of

sensitivity of each prothoracic gland to neurosecretion, and in the ability of each insect to adjust to the effects of the operation and to utilise remaining intact nervous pathways for the release of neurosecretion.

Towards the end of the stadium the locust sets in motion a sequence of events which culminate in the process of ecdysis, during which the insect sheds the old cuticle and expands the underlying newly developed one to its full size. The cessation of feeding, the emptying of the gut of food, and the swallowing of air constitute the aforesaid sequence.

The cue for cessation of feeding is not known in any insect, but its effect must be to elevate the taste threshold to a level which causes the insect to become unresponsive to the presence of food. The mechanism involved in maintaining an elevated taste threshold level over the moulting period may be similar to that deduced by BERNAYS and CHAPMAN (in press) following a single feed. These authors conclude that the filling of the foregut stimulates, by way of nerves of the anterior stomatogastric nervous system, the release of a hormone from the storage lobes of the corpora cardiaca. This hormone acts on the terminal sensilla of the palps, causing them to close and so increase their resistance levels. Thus, immediately after the consumption of the last instar meal the palp tips will exhibit a high taste threshold level. At this time the insect has already decided to completely empty its gut of food and, as the X-ray studies revealed, the moment food starts to leave the foregut air begins to enter through the mouth.

In this way some degree of stretch in the foregut is maintained and this, according to the hypothesis of CLARKE and LANGLEY (1963d), stimulates the continued release of hormone from the corpora cardiaca, which reaches a high titre in the absence of any food absorption. The circulating hormone, in addition to stimulating the prothoracic glands as CLARKE and LANGLEY suggest, may also serve to maintain the palp tip resistance at a high level. After ecdysis the movements of the foregut become less strenuous, the amount of hormone released diminishes, and eventually the palp tip resistance level falls to a value low enough to permit resumption of feeding. HILL and GOLDSWORTHY (1968) have shown that in fourth and fifth instar Locusta nymphs the development of the new cuticle takes place during the last 24 hr or so of the stadium, when feeding activity has ceased. It is possible that one and same cue halts feeding and stimulates old cuticle resorption and new cuticle deposition.

Food can continue to move through the gut unhindered in some frontal ganglionectomised animals during the feeding period but these same operated animals are unable to empty the gut of food at the end of the stadium. This paradox can perhaps be best explained by assuming that the brain plays no major part in the control of food passage during the feeding period, but does play a significant role in initiating, and perhaps even controlling, the process of gut emptying prior to air swallowing. The cerebral influence is mediated primarily at the level of the frontal ganglion (via the frontal connectives), but possibly also at the level of the

hypocerebral ganglion (via the NCC I, STRONG, 1966a), which in turn influences the ingluvial ganglia (via the outer oesophageal nerves). The cutting of both frontal connectives does not prevent normal emptying of the foregut in the vast majority of those animals attempting to moult to the adult stage. Presumably after this operation the frontal ganglion receives cerebral information via the NCC I, hypocerebral ganglion, recurrent nerve pathway. Neither is emptying of the foregut hampered by the lack of a direct nervous connection between the frontal ganglion and the pharynx, following severance of the pharyngeal nerves. Clearly other nerve pathways, such as the branches of the frontal connectives and the branches of the recurrent nerve, are relaying the motor information to the pharyngeal musculature.

Air swallowing at ecdysis is also under cerebral control. The operations of both frontal connective severance or anterior, median and posterior pharyngeal nerve severance interfere with the process of air swallowing and in all cases prevent a successful moult to the next stage. The moult fails because the operated animals are unable to swallow and/or retain sufficient air in the foregut to facilitate successful splitting of the old cuticle. Presumably the same nervous pathways as those mentioned above, in the context of food removal, carry motor information from the brain to the pharynx, thus permitting at least some air to enter the foregut following frontal connective or pharyngeal nerve severance. In addition some air will probably enter the foregut by passive diffusion.

LANGLEY (1962) found that operations involving the removal of the frontal ganglion, the cutting of both frontal connectives or the separation of the frontal ganglion from the surface of the pharynx caused the operated animals to lose water through the intersegmental membranes. This loss was thought to be due to the non-replacement of the proteinaceous components of the cuticle worn away as a result of the friction created by the intersegmental membranes rubbing against each other. CLARKE and GILLOTT (1967a) suggested that the low level of amino acids and proteins in the haemolymph of frontal ganglionectomised animals was the root cause for this water loss, the decrease in the concentration of these substances leading to a breakdown in water balance. Observations made during the present study, however, support the contention of ROOME (1968) that the 'water' is, in fact, regurgitated digestive fluid and grass juices which leak to the exterior from the mouth.

In accordance with LANGLEY the only operations causing 'leaking' are frontal ganglionectomy, both frontal connective severance, and pharyngeal nerve severance. The regurgitated fluid can be detected in the region of the mouth-parts and neck membrane as early as 2 days after the operation, timing that coincides with the provision of the first post-operative meal. ROOME suggests cerebral control of digestive fluid retention and this is the view taken here, the motor nerve pathways involved being the same as those controlling air intake and/or retention at ecdysis.

ACKNOWLEDGEMENTS

The author wishes to express his gratitude for the guidance and encouragement of Dr. K.U. Clarke, who supervised this work.

He would also like to thank Professor E.J.W. Barrington for making available the facilities of the Zoology Department, without which this investigation would not have been possible; Mr. R. Searcy for his help with the photography, Mr. R. Gilder and his staff for providing readily available stocks of locusts, and Mrs. R.B. Richardson who typed this thesis.

Finally the author is indebted to Dr. R.F. Chapman for the use of library facilities at the Centre for Overseas Pest Research, London.

APPENDIX

The figures and summary tables presented in Chapter III were compiled from the raw data given on the ensuing pages.

All weights are expressed in milligrams; ages and times are given in days unless otherwise stated.

The following abbreviations have been used:

B.R. = before ringer.

A.R. = after ringer.

D = dead animal.

$\underline{976}$ = weight of newly moulted animal.

$\underset{\cdot}{9}\underset{\cdot}{0}\underset{\cdot}{1}$ = weight of animal at time of attempted moult.

* = displacement of labrum, caused by food accumulating in the preoral food cavity.

S.E. = standard error.

n.s. = values not significantly different (see 't' tests).

M, m. = male animal.

F, f. = female animal.

Schedule for Intra-vitam Methylene Blue Staining of Insect Nerves

(After STARK et al., 1969)

A. Solutions

1. Methylene blue stock solution

Dissolve 0.5 g methylene blue chloride in 100 ml distilled water. Heat the solution and stir until the solid is dissolved. Filter, cool and store.

2. Reduced (leuco) methylene blue solution

To 30 ml methylene blue stock solution add 6 drops concentrated HCl and 6 ml of 12% (w/v) Rongalit (Gurr Ltd.) solution. Stir and warm the mixture gently until it begins to turn a deep, dirty green colour, then remove from the heat and stir until colourless. Filter, after cooling, and store in the refrigerator in a tightly stoppered 40 ml bottle.

3. Fixative

8% (w/v) ammonium molybdate solution. Keep refrigerated and use cold.

B. Sequence

1. Inject 0.15 ml reduced methylene blue solution into the locust as described in Chapter II J and leave for 1 hr.

2. Open the insect under cold 8% ammonium molybdate (as previously described) and leave for 24 hr at 0°C.

3. Dissect out the appropriate portion of the nervous system and wash it thoroughly in several changes of distilled water.

4. Transfer to a drop of dilute glycerin albumen (Gurr Ltd.) solution on a coverslip. Remove excess fluid, orientate as desired and let partially dry in the air until the preparation is firmly attached to the coverslip. Keep the coverslip in a horizontal position for the remaining steps.

5. Dehydrate in two changes of tertiary butyl alcohol (1-2 hr each).

6. Clear in two changes of xylene (15 min each).

7. Apply the coverslip to a slide with synthetic resin (DPX).

Schedule for Preparation of Material for Examination Under the Electron Microscope

(After SMITH and SMITH, 1966; ANSTEE, 1968)

A. Preparation of Buffer and Fixatives

Note: Double distilled water and 'Analar' grade chemicals employed throughout. All solutions kept refrigerated at 0°C.

1. 0.1 M phosphate buffer, pH 7.4

Dissolve 15.6 g $NaH_2PO_4.2H_2O$ in 1 litre of distilled water (Solution A).

Dissolve 35.8 g $Na_2HPO_4.12H_2O$ in 1 litre of distilled water (Solution B).

To 190 ml Solution A add 810 ml Solution B to give 1 litre 0.1 M phosphate buffer, pH 7.4.

2. Addition of sucrose

To make 0.17 M sucrose solution in 0.1 M phosphate buffer, pH 7.4, dissolve 58.14 g sucrose in 1 litre of buffer.

To make 0.34 M sucrose solution in 0.1 M phosphate buffer, pH 7.4, dissolve 116.28 g sucrose in 1 litre of buffer.

3. 2.5% glutaraldehyde solution

A specially purified and stabilized 25% solution of glutaraldehyde for use in electron microscopy was obtained from TAAB laboratories. The 2.5% solution of glutaraldehyde used for fixation was prepared by adding 1 part of stock solution to 9 parts of 0.1 M phosphate buffer, pH 7.4, containing 0.17 M sucrose.

4. 1% OsO_4 solution

0.1 g OsO_4 was dissolved in 10 ml 0.1 M phosphate buffer, pH 7.4, containing 0.34 M sucrose. When not in use this solution was kept frozen.

B. Preparation of Araldite Monomer

CIBA Araldite epoxy resin CY212(M)	10 ml	Araldite monomer
CIBA Araldite hardener HY964	10 ml	
BDH Dibutyl phthalate (plasticiser)	0.8 ml	

To set monomer add:

CIBA Araldite accelerator DY064 0.45-0.50 ml

C. Fixation

1. Fix tissues for 2 hr at 0°C in ice-cold 2.5% glutaraldehyde in 0.1 M phosphate buffer, pH 7.4, containing 0.17 M sucrose.

2. Replace fixative with 0.1 M phosphate buffer, pH 7.4, containing 0.34 M sucrose and wash overnight. Dissect out the required tissue at this stage.

3. Wash again in fresh buffer solution.

4. Post-fix for 1 hr at 0°C in 1% OsO_4 in 0.1 M phosphate buffer, pH 7.4, containing 0.34 M sucrose.

5. Wash in two changes of buffer at 0°C (15 min each change).

D. Dehydration

6. Dehydrate at 0°C in 50%, 70% and 90% ethanol (30 min each change). Tissues may be left overnight in 70% ethanol.

7. Transfer to cold spectroscopically pure absolute ethanol containing 1% uranyl acetate, freshly prepared and Millipore filtered before use. Leave for 1 hr at room temperature.

8. Wash in fresh spectroscopically pure absolute ethanol for a further 1 hr at room temperature.

E. Embedding

9. Place in 25% Araldite monomer (made up in spectroscopically pure 100% ethanol) for 1 hr at room temperature.

10. Transfer to 50% and 75% ethanolic monomer solutions - 1 hr in each at room temperature.

11. Embed in 100% Araldite monomer for 1 day at 48°C.

12. Transfer tissues to Araldite monomer + accelerator for 1 day at room temperature.

13. Move into Araldite monomer + accelerator for a further 1 day at room temperature.

14. Transfer the material into dry, clean BEEM capsules which immediately prior to this have been filled with fresh Araldite monomer + accelerator. Polymerise in an oven at 90°C for 2 days. At the end of this time the blocks are ready for sectioning.

Note: Tissues requiring special orientation, e.g. nerves, were embedded in the lids of BEEM capsules.

TABLE I

Daily body weight changes of adult male and female Locusta used in Section I of Chapter III.
